Insanity in Lead Workers; Acute Delirious Mania.—Robert Jones concludes: (1) That lead poisoning is a contributory factor in the causation of insanity, and that in lead workers there is a higher average number of general paralytics than in others of the population; (2) that there is a tendency in these cases to cardiac, renal, and arterial degeneration with complications due to syncopal or epileptiform fits; (3) that most cases present marked signs of anæmia and ill-health, with unsteadiness of gait and general impairment of muscular strength and very frequently a history of temporary failing vision; (4) that the mental symptoms may be grouped among one or other of the following varieties: (*a*) those in the nature of toxæmia and with sensory disturbances, and which tend rapidly to get well; (*b*) those with hallucinations of sight and hearing more chronic in their nature, and which may be irrecoverable. The delusions in this class are almost invariably those of being poisoned or followed about, and are in the main persecutory; (*c*) those resembling general paralysis with tremors, increased knee jerks, inco-ordination, and accompanied with listlessness amounting to profound dementia, but which tend to get well; (5) and that in most lead cases presenting mental symptoms the tendency is to recovery unless the patient dies early.

Some Cardio-Psychical Associations.—J. R. Whitwell states that we may, perhaps, with some reserve for further observations accept a certain series of cases of imbecility as due to disproportion between the development of brain and cardiovascular system; here, the mental symptoms, as a result of this imperfect evolution, are entirely on the lower plane of psychical reactions. Another class is one in which congenital or early infantile heart disease of serious type is present the proportionate cardiac development being normal, and compensation being more or less properly carried out. Certain cases of mitral disease present symptoms of gloom and depression, as well as self-absorption, suspicion, and irritability. In conclusion, the writer notes the condition of pathological eupathy in which the heart at last, refusing to respond to ordinary cardiac stimulants, gradually fails beyond recovery. Yet the patient is convinced that he is better and stronger daily.

Acute Delirious Mania.—John Turner believes that all forms of acute delirious mania are of toxic origin, some being caused by the introduction of a poison from without, others by the absorption of septic material, while a third class is due to auto-intoxication. As regards the action of a possible poison on the nerve cell and its functions the subject is too speculative for any advantage to be derived from discussing it. In cases with high delirium and a rapidly fatal termination there is generally a condition present in which all the giant cells are profoundly altered, and probably the inspection of a section in such cases would furnish a tolerably accurate diagnosis of the mental state preceding death.

The Effects of Inhalation of Certain Anæsthetics on the Kidneys.—Dudley Buxton and A. G. Levy quote cases which show that the quantity of urine, after the administration of ether, was reduced in amount. However, the routine preparatory treatment may have had considerable influence in bringing about this result. This reduction is in the urinary water only. There is little evidence to show that ether exerts directly any deleterious influence on the kidney parenchyma. The administration of this anæsthetic, however, should be performed with care, and an undue quantity should not be given.

Death following Psychical Trauma, with Observations on the Delirium Nervosum of Dupuytren and Operative Psychoses.—Pagenstecher describes an interesting case of litigation against an accident insurance company. The patient, a man aged fifty-one years, who was somewhat neurasthenic but otherwise in good health, was heavily insured in a number of accident companies. While sharpening a pencil he slightly cut the ball of his thumb, his pen at the same time falling from behind his ear and covering the little wound with ink. The patient became greatly alarmed lest blood poisoning set in, and consulted several physicians with the idea of having the arm amputated. Simple antiseptic treatment was applied, but the patient insisted on the idea of infection, complained of pains ascending the arm as the process progressed, and went into syncope, followed by a restless night and severe delirium, with agitation and convulsive symptoms the next day. There was no fever or rise in pulse rate, and the patient came to himself when addressed, but suddenly, without any change in the symptoms he went into collapse, and died thirty-two hours after receiving the injury. On autopsy nothing explaining the fatal ending could be found; ptomain or other poisoning was excluded by proper investigation of the internal organs. The case is one of traumatic delirium, such as is observed after accidents and surgical operations which are often comparatively trifling and out of all proportion to the resulting mental derangement, the gravity of the condition depending not on the extent of the injury but on the state of psychical shock. In the case in question death was probably due to an acutely supervening attack of cardiac insufficiency. The decision of the courts has not yet been rendered.

First Aid by the Laity in Lime or Mortar Injuries to the Eye.—H. G. Stutzer considers irrigation with water as the best and most easily applicable remedy to be entrusted to lay hands in injuries of this sort. Sugar solution has been recommended, but though lime is slightly more soluble in this medium than in pure water, it forms a pasty mass with it which is hard to remove. Oil or milk lessens the pain but does not check the destructive action of the foreign substance; glycerin gives good results but is not adapted for a first-aid remedy, as it is not always quickly obtainable, and in these cases speed is the first consideration. The following directions with suitable illustrations should be printed on placards and posted about all buildings in course of construction. The patient is at once to be laid on the ground, and any convenient vessel quickly rinsed and filled with clean water. A fellow-workman kneels at his side, and opens the injured eye by applying the thumbs to the two eyelids and forcibly separating them. At the same time some one else pours the water into the eye in as fine a stream as possible, holding the vessel at the height of one and one-half feet and continuing as long as any particles are still to be seen in the eye. Then the patient should be brought under medical care as soon as possible.

Cured Peritoneal Tuberculosis in Children.—Cassel says that while it is now universally recognized that operative treatment is the proper measure in this disease in adults, the same conclusion is not so unreservedly applied when the patients are children. In his experience, however, no distinction should be made on the ground of age, and he presents three case histories in which a cure effected in this way has persisted for several years. Whenever in patients of this class, in spite of a suitable general and hygienic regimen, including the application of the proper external and internal remedies, a febrile movement continues during several weeks, the abdominal swelling does not diminish but increase, and the emaciation continues to progress, the case is a suitable one for operation, no matter what form of peritoneal tuberculosis it may be.

Berliner klinische Wochenschrift, September 3, 1900.

Eye Injuries from Lime.—H. Schmidt-Rimpler analyzes fifty-six cases seen during the last ten years. The immediate procedure in these cases should be the careful removal of all particles of lime from the cornea and pupil. This is best done with a piece of clean linen dipped in oil, or, if no oil is at hand, with a piece of linen alone. The accidental abrasion of the epithelium is of less danger than the continuance in the eye of the offending body. Next the eye should be thoroughly syringed with some bland oil, care being taken that the oil penetrates thoroughly under the upper lid and in the conjunctival sac of the lower. The writer advocates the use of spectacles by those whose occupations render them liable to this class of injuries.

Treatment of Lepra.—W. Donitz advises the subcutaneous injection of the familiar chaulmoogra oil. The injections should be repeated every ten to fourteen days, using for dosage 0.1 to 0.2 gm. A reaction similar to that of injections of cantharidin has been observed. Some subsidence of the affected areas was observed.

A New and Simple Method for the Observation of Injury to Living Cells and Organisms (Bioscopy).—Neisser and Wechsberg, in conducting an investigation on staphylococcus toxin, had occasion to study the action of leukocidin on leucocytes. In doing this advantage was taken of the reducing power of the cells to avoid the necessity for the time-consuming direct inspection with the oil-immersion lens. If to a fluid containing numbers of living leucocytes a small amount of methylene-blue solution be added in a test tube sealed with paraffin, and the mixture be placed in the thermostat, in a short time decolorization of the fluid will take place. If, however, the leucocytes be killed by the addition of leukocidin, quinine, or overheating, the solution retains its color, showing the absence of vitality in the cells. The reaction succeeds with all cells capable of surviving, such as kidney and pancreas cells, as well as the motile leucocytes, spermatozoa, and ciliated epithelium. Under similar conditions many forms of bacteria give the same reaction, which is especially strong for tubercle and typhoid bacilli, cholera vibrios, and staphylococci.

A Method for the Demonstration of a Capsule in Bacteria Grown in Non-Liquid Media.—Icilio Boni concluded that

the reason that the capsule of the pneumococcus was visible in stained specimens that had been grown on bouillon, but not in those cultivated on agar, was that the capsule being colorless depended for its differentiation on the contrast afforded by the staining of the slight film of bouillon; bacteria taken from solid cultures are spread in a drop of water which affords no background on drying. Better than bouillon for mounting bacteria to be stained with the object of showing the capsule is a solution of the yolk of one egg in 50 gm. of glycerin, with the addition of two drops of formalin. By using this fluid it is possible regularly to identify the capsule of bacteria which under the older methods do not always show it, and it is probable that by its means capsules will be detected about bacteria now not supposed to have them.

The Prevenion of Puerperal Fever.—Hofmeier enters a strong plea for greater thoroughness in the sterilization of the operative field in obstetrical work. While the necessity for asepsis is great at all times, whenever any operative interference is proposed, such as manual extraction of the placenta, it is absolutely essential that a thorough sterilization of the vagina itself as well as the vulva be carried out.

French Journals.

Thyroid Cancer.—A. Carrel at the close of an interesting paper on this subject states that death is the fatal termination of the evolutiou of cancer of the thyroid body. It may be due to the progressive cachexia, or to respiratory, vascular, or infectious complications. In the majority of cases the local conditions assume the chief importance, but now and then, especially if the tumor be very malignant, cachexia holds the first place. Most frequently, however, tracheal compression causes death, and often suddenly, by asphyxia. Death from vascular complications is rare, although certain examples of extreme hemorrhage from ulceration of the carotid artery are quoted. The various infections find a fertile soil in the respiratory apparatus of the victim of this malady.—*Gazette des Hôpitaux*, September 18, 1900.

Indications and Operative Technique of Gastrostomy for Œsophageal Neoplasm.—M. Mauclaire states that the prognosis of œsophageal neoplasm is most grave, and as the removal of the growth is not practicable, palliative treatment only is left to the surgeon. The writer then briefly reviews the history and chief methods of gastrostomy. The results of this operation are not so brilliant as one could wish, but nevertheless the lesion improves so much that sometimes food can again be taken by the mouth. Life is prolonged for weeks or months, pain is diminished, and the patient is greatly relieved.—*Le Bulletin Médical*, September 12, 1900.

Sternal Adenitis.—Maurice Patel, after discussing this subject, concludes that sternal adenitis falls into three groups due to the anatomical position, whose principal symptoms are as follows: (1) Deep adenitis, phenomena of constriction, extension to the mediastinum and the axilla; (2) medium adenitis, no phenomena of constriction, position substernal, deep cicatrix, retrosternal; (3) superficial adenitis, position presternal, cicatrix presternal, superficial.—*Gazette Hebdomadaire*, September 16, 1900.

Subconjunctival Injections.—M. Étiévant shows that by subconjunctival injections of mercurial solutions, the antiseptic substance by means of the lymphatics penetrates to the infected parts and exercises its action directly there. The writer believes that the results of this method are most successful, and that accidents do not attend it.—*Gazette des Hôpitaux*, September 15, 1900.

The Journal of Tropical Medicine, September, 1900.

The Use of Quinine in Malarious Fevers.—Rai Kailas Chunder Bose Bahadur, of Calcutta, relies absolutely upon quinine in the treatment of malarious fevers, always obtaining satisfactory results. He considers it simply a waste of time to wait for a remission or perfect intermission, for one cannot be positive about the prognosis, however mild the case may appear at the onset, apparently uncomplicated cases sometimes assuming a pernicious form and killing the patient. The use of quinine during the hot stage of fever has often been followed by hopeful results. In remittent fever it should be given in small repeated doses, as big doses are apt to cause sickness, insomnia, and depression of spirits. Failure of the heart's action may be prevented by the judicious administration of quinine from a very early stage of the disease. Intermittent fevers yield rapidly to the remedy: one dose of gr. xv. shortly followed by another similar dose rarely fails to cut short the fever and prevent its return. The author reports several cases.

Malignant Malaria, with Urticarial and Petechial Eruptions.—Charles Todd reports the only one of seven hundred cases of malaria seen by him in Mashonaland in which urticaria was observed. The rash appeared first, and the case was regarded as one of ptomain poisoning, probably due to tinned food; but other persons who had partaken of the same dishes did not suffer. The successive crops of urticaria, coupled with the fact that the patient's condition was gradually becoming worse, suggested that the poison producing these symptoms was still being formed in the body, and the appearance of coma and a petechial eruption pointed to malaria as the cause. Malarial parasites were found in the blood. Hypodermic injections of the acid hydrochloride of quinine caused an improvement in the patient's condition, but on the next day death occurred from heart failure, the temperature reaching 104° F. immediately before death.

On Plague and its Dissemination.—By Frank Tidswell.

Zeitschrift für klin. Medicin vol. xl., Nos. 5 and 6 1900.

The Influence of Morphine on Gastric Secretion.—F. Riegel in view of extensive experiments on men and animals believes that the universally accepted belief that the secretion of gastric juice is inhibited by the administration of morphine rests on errors of observation, and that the therapeutic use of this agent in conditions in which the object is to diminish the secretory activity of the stomach is ill advised. On the contrary, morphine given either when the patient is fasting or with the food causes an increased pouring out of gastric juice, though—and this perhaps explains the former idea—there is a considerable latent period before this result makes itself manifest. This conclusion applies only to cases in which the drug has been given for a short time; whether it would still hold true after its habitual use for a considerable length of time is not certain. But even if this question remains an open one, still the advice that, owing to its property of checking secretion, morphine be administered in cases in which even the normal hydrochloric acid is injurious, especially in gastric ulcer, is certainly to be condemned. On the contrary, reflecting on the results of these experiments, it would seem that caution should be exercised in selecting morphine as an anodyne in gastric affections, and it should be administered only in cases in which an increased secretion cannot do harm. The results of further experimentation have shown the author that atropine and belladonna preparations do have to a high degree the faculty of reducing the amount of gastric juice, and this fact explains the clinical observation that the addition of a small amount of atropine often gives relief when the injection of morphine alone is powerless to control gastric pain.

The Mechanics of Memory.—Adamkiewicz regards memory as a purely physical function underlying and in some sense forming the basis of the psychical life, but still in its nature as separate and distinct from it as any other of the purely vegetative processes. Judged by a standard of efficiency memory is most developed in childhood, decreases during adult life, and is least active in old age, while hand-in-hand with these functional alterations go organic changes in the brain substance. In infancy and early life the brain tissue is extremely tender and vascular, but with increasing years its blood supply diminishes and it grows coarser in texture. The ability of young children to acquire large numbers of disconnected and irrelevant facts with an ease and accuracy quite out of the power of their elders is well known but no one would maintain that they are therefore on a higher psychical plane, and it is a matter of every-day experience that after a few years the same individual, though undoubtedly much farther advanced intellectually, is unable to perform the same feats he formerly accomplished without effort.

The Study of the Cerebrospinal Fluid.—M. Lewandowsky says that in view of the increasing interest attaching to the subdural injection of drugs, and especially the cocaine anæsthesia of Bier, and the direct injection of tetanus antitoxin, it is of importance to recognize fully the nature of the cerebrospinal fluid. In general it may be said that this partakes of the nature of the lymph, receiving only a small portion of transuded matter and this after modification through the specific action of the cerebral capillaries. On the whole it is to be regarded as a specific product of the brain, and represents that part of the lymph originating through organic action. Experiments with strychnine and ferrocyanate of sodium showed

that when thrown into the subdural space these substances penetrated directly into the nerve substance through its lymph channels and without the intervention of the circulation.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PLAGUE AT GLASGOW—WAR HOSPITALS—SIR R. BULLER AND LORD ROBERTS DEFEND THE MEDICAL SERVICE—ALLEGED CRUELTY TO A LUNATIC—THE NATIONAL HOSPITAL SCANDAL—PROFESSIONAL PHILANTHROPISTS—SOME BOOKS—COMING SESSION.

London September 14, 1900.

Glasgow has had a trying week but has not given way to panic. Her sanitary authorities are wide awake and active, but the name of plague naturally causes fear, and in addition to the direct danger from disease there is the serious injury to commerce. On Monday and Tuesday the cases of plague numbered sixteen; there were two doubtful and one hundred and thirteen persons under observation. These numbers have not increased. It was announced that one of Monday's admissions was a case that had existed undetected for many days in the infected district. This gives rise to misgivings lest during that time the infection may have spread from it. Further accommodation is being provided for doubtful cases, and no precautions will be omitted. In this respect I may remark that for months past the medical officers of health have adopted precautions against the arrival of infection, such, for instance, as scheduling the arrival of ships from infected places at any of our own ports. Inquiry has been made as to the condition of such ships, the water supply on the voyage, the nature of their cargo, whether any dead rats have been found, and the health of the crew and passengers. By intercommunication among the health officers of our several ports the most important information is circulated.

The sensational press has done its level best to get up "a scare" about plague, but fortunately with little success, although a statement was made that cases had appeared in the London docks—a statement for which there was no foundation. It would not be at all surprising should cases find their way to this port, but the port sanitary authorities are confident that they will be able to deal with such a case and prevent it spreading. Should a case ever pass their lines it would almost certainly reach the Seaman's Hospital, where the staff are well prepared for such a contingency, and the Tropical School would second them. Mr. Canthe, F.R.C.S., who had experience of the disease at Hong Kong, has visited Glasgow and published his conclusion as to the outbreak in the local journals. Dr. Colvin, who saw the first cases, has recorded their clinical features in *The Lancet*. Dr. Chalmers, the medical officer of health, has invited the local profession to a series of clinical demonstrations on plague to be given by the physician-superintendent of the Belvedere Fever Hospital, which is being utilized for the plague cases. This is a specially commendable step, considering that early diagnosis is so essential to prevent the spread of the disease, and scarcely any practitioner has had an opportunity of studying it. All those who have experience of the disease and have seen the cases at Glasgow agree that they are very mild, but this, of course, does not make the infectiveness any less. A large supply of plague serum has been sent by the Pasteur Institute, and any amount can be obtained. It is asserted that the institute has stock enough to inoculate the population of the continent; but it seems improbable that such a quantity should have been accumulated, for its keeping qualities are not to be trusted. Probably the report is due to a statement that the institute could obtain a supply to meet an epidemic extending over all Europe.

The Royal Army Medical Corps must await the verdict of the commission as to the way in which it met the demands made upon it. The corps can wait patiently. Not so the "plague of women" or the sensational M.P. Lady Sykes, who wrote some "sidelights on the war," has repeated in *The Daily News* the unsupported charges in which she indulged, and in the repetition has "gone one better." Mr. Murray Guthrie, M.P., not satisfied with giving evidence before the commission, has added to it an article in the *Nineteenth Century* magazine, where, of course, he cannot be cross-examined. He imputes the blame of any defects to the Royal Army Medical Corps, and casts out his charges and insinuations as confidently as if he possessed a knowledge of what he is writing about—a qualification which he evidently lacks.

Mr. Lees Knowles, M.P., has brought upon himself a crushing rebuke from Sir Redvers Buller, who in reference to his charges asks, "Was ever a more shameful accusation more shamelessly published?" Mr. Knowles was challenged by Sir Redvers to substantiate his slanders or withdraw them, and has accordingly climbed down. His bid for popularity will therefore prove of little avail, and other M.P.'s may well take warning. But it seems a sad indication of public veracity when members of parliament and spiteful women disseminate slanders for the sake of getting temporary notoriety. It is not every slander that is so easily scotched, and it is not every general who can be expected on every occasion to speak out. All honor to the man who does!

Lord Roberts has given evidence to the commission and told how he ordered the transport to be cut down as an imperative necessity. That was of course understood, but it is more to the point to have his lordship's testimony as to the medical care of the sick and wounded. He told the commission they were sent down from the front with the least possible delay; that he frequently visited the hospitals, and was satisfied that both the army and civil doctors did their duty well. Perhaps after this the newspapers will be ashamed to circulate one-sided assertions libelling a body of men who cannot reply, but whose defence must await the report of the commission.

A painful case of alleged cruelty to a lunatic has excited much attention. The patient was a congenital idiot and resided with his brother, who is a medical man, a sum of £80 to £90 being allowed for his maintenance. When his habits became unbearable in the house, a harness-room at the end of the stable yard was furnished as a bedroom, and an enclosure also fenced off and partly roofed over for a day-room. The only attendant seems to have been the defendant's coachman, who was fined £5 for cruelty. The defendant himself escaped, as the magistrate who inspected the place thought that reasonable care had been taken by him, and that the allegations of cruelty against him were without foundation. It was admitted that a cane had been used to frighten the patient and to chastise him lightly. The defendant may be thankful that he has been acquitted. He will probably suffer much in costs and regret. Though the patient was taken charge of at the wish of the family for a nominal sum, he was surely entitled to more consideration. Obviously he ought to have been in an institution where he would have been properly attended to. It was not a fit case for private care. It is an object lesson, too, on the necessity of communicating to the lunacy commissioners all cases of boarding lunacies.

Sir J. Crichton-Browne has engaged the "secretary-director" of the National Hospital for Paralysis in a correspondence which illustrates the sort of tactics resorted to by the board. It comes out that the special meeting was intended to be at an inconvenient time to the staff and others; that the statement of facts admitted at the meeting to be incorrect is still being circulated; that the meeting was packed, though the packing secured the presence of only sixteen voters. Even proxies were sent out—not to all governors, however, for the secretary-director says, "Naturally the board did not send proxy papers in support of their policy where it was known they would be unwelcome." In another letter he even says it would have been "an impertinence to solicit the support of friends of the staff." Sir J. Crichton-Browne then asked how these were discriminated in the distribution of proxy papers? This is the way the board carry on their campaign against the staff.

You will not be surprised to hear that the true inwardness of the situation relates to the question of paying patients at hospitals, as well as to the rights of the staff to a voice in the government. The latter is the better position to fight, but the former is the one that most interests the mass of the profession. The professional philanthropists are sure to be generous at the expense of the practitioners, and generally are very wroth if their views are questioned. They want to speak with authority, and when they have no case abuse the other side. Even the Hon. Sidney Holland, who tries to pose as a friend of the profession as well as a philanthropist, when he finds a letter in the *Medical Press* from an indignant practitioner to which he can give no adequate reply flies off at a tangent, accuses the writer of being "exceedingly discourteous," and by way of teaching him by example, hopes "he is not as ill-mannered in his consulting-room as he is in his correspondence." Now, why should this hospital question excite the anger of those who profess so much charity and good-will?

Major G. M. Giles, I.M.S., M.B. London, has published a work which at the present time must attract attention. It is entitled "A Handbook of the Gnats or Mosquitos, Giving the Anatomy and Life History of the Culicidæ." It is a volume of nearly four hundred pages, and the descriptions are clear, though as much can hardly be said of the illustrations. These the publishers should improve in a second edition, which will probably be called for. Another timely publication is "Besieged by the Boers: a Diary of Life and Events in Kimberley during the Siege," by E. Oliver Ashe, M.D. London, F.R.C.S. Sir Joseph Fayrer's "Recollections of My Life" is a much larger production, and one which every medical man who has the opportunity will be pleased to peruse. Professor Montenegro's work on "Bubonic Plague" has been translated by Dr. Munro. It contains notes on the cases in Oporto, and the author has written an appendix expressly for the English translation.

The coming season is casting its shadow before it, and many teachers are back from their holidays and thinking about the dinners or introductory lectures, or more probably the entries of new students.

And with this shadow comes a foretaste of winter—after our heat and sunshine. There is a nip of frost in the mornings and evenings—almost an October weather.

STERILIZATION OF RUBBER GLOVES.

To the Editor of the Medical Record.

Sir: In the Medical Record of September 15th, under the head of "Surgical Suggestions," Dr. Richardson's method of sterilizing gloves is described. While I was an interne at Bellevue Hospital rubber gloves were used extensively in the wards of Dr. J. R. Hayden, and the following simple and thorough method of sterilizing them was adopted: The gloves were filled with gauze, each finger being carefully packed so that two layers of rubber were nowhere in contact. They were wrapped separately in several layers of gauze and were boiled in plain water for twenty minutes. From this they were transferred to cold bichloride solution 1:2,000, where they were left until ready to use. The difficulty experienced in putting on wet gloves was easily overcome by filling them with solution, allowing the hand to force it out as the gloves were drawn on.

E. L. Kellogg, M.D.

New York, September 20, 1900.

THE WEARING OF EYEGLASSES.

To the Editor of the Medical Record.

Sir: Observing that Dr. Jenkins seems to have misconstrued my criticism, in which I differ with him as to the "continued" or the "interrupted" wearing of lenses when ametropia or anomalies exist, I beg your forbearance in permitting space for the following propositions, which I present as the gist of my opinion upon the question under controversy:

(1) The entire solution depends upon the question whether an eye has been corrected right or wrong, *i.e.*, making the eye normal or abnormal. That an improper correction should be worn "as little as possible" is self-evident; again, if you can make an abnormal eye normal, why limit the time as to the keeping of that eye normal?

(2) Ametropia, like other structural defects and abnormalities, is followed by functional disturbances and sequences such as scowling, frowning, squinting, nictitation, eye strain, asthenopia, neurasthenia, heterophoria, strabismus, anisometropia, amblyopia, mental disturbances, etc. Why the cause of these disturbances should be removed only "as little as possible" is a matter of sufficient gravity to warrant either a thorough confirmation or denunciation.

(3) A myope of a fair degree of myopia has, beyond reading distance, defective vision, and when the myopia exceeds two or three diopters his vision is exceedingly bad, excluding him from various vocations. He can do considerable near work without glasses, but he cannot completely avoid muscular unbalance and its resulting discomfort. This person's vision can be made practically perfect and his annoyance relieved if properly corrected for both near and far vision, and why in the name of common sense this person's comfort should be interrupted merely to foil the "caricaturist" is a strange demand. Why should he not see well all the time?

(4) An hyperope of about three or four diopters defect in youth can overcome by extra exertion this defect so that he can see practically normally. But as the near point recedes his power and scope of exertion "diminish," so that in time when his accommodation = o he will need a plus lens as badly as the myope needs the minus lens, and without this lens his vision for distance is as poor as the myope's vision with an equal degree of myopia. He may develop hypertrophy of the accommodation muscle (as strabismus and what not), but in time his presbyopia will extend to infinity, and he will need lenses as badly to tell his friend across the street as he does to read the type before his nose, only less in degree. All ordinarily informed ophthalmologists know that such degrees of hyperopia left uncorrected are prolific factors in the causation of muscular unbalance, amblyopia, etc. But why should not this hyperope see well all the time as well as part of the time? The answer lies in the proper correction.

(5) The individual with even an ordinary amount of astigmatism has bad sight, while only a few diopters of this defect give him miserable sight. That this is a fertile etiological factor in amblyopia is little disputed. Why such individuals should go about guessing at objects part of the time, carrying their lenses in pocket or hand, holding them before the eyes "as little as possible" (*sic*), encouraging the bad, inevitable sequels as much as possible, is not in harmony with either modern or "antiquated tables" of refraction. To encourage this, to me seems analogous to encouraging grape-seeds to remain in the appendix.

(6) Let me emphasize that when we deal with muscular and refraction anomalies we are facing a structural condition *per se*, with but rare exceptions. A "functional" refraction error I do not consider a refraction error proper, but look upon it as a symptom or sequel of some other trouble. If this is confusing "function with structure," I prefer confusion. No qualified oculist corrects insignificant and harmless errors.

T. T. Blaise, M.D.

Mason City, Iowa.

THE LATE DR. FRANK C. MERRIAM.

To the Editor of the Medical Record.

Sir: Frank C. Merriam, whose death is recorded in this week's Medical Record, deserves particular mention because of certain traits which characterized him. His intellectual honesty was uncommon, and he took pains to think for himself. He was not aggressive. He did not strain to force his opinions on others. He sought to be on the right side with facts as they are. He took no pride in differing from others for the mere sake of appearing to be an independent thinker. He was a studious as well as an active practitioner.

In many of the jubilee and holiday addresses of medical presidents the medical practitioner has become a good deal lost behind the glorification of the progress of scientific medicine. Our era is one of Sturm-und-Drang therapie. Now and then, however, a medical orator will be bold enough to say that the general practitioner has become "too reverent for authorities and scarcely believes the evidence of his own senses, if it conflict with what the books say." Dr. Merriam did not disregard authority. Not even the cutest and wisest practitioner can afford to do that. But Dr. Merriam held his authorities accountable to proper logical divisions, and definitions controlled by facts and historical data. He was a large-hearted and sympathetic man, but he did not fail to distinguish between the results he wished and hoped for and those which nature grudgingly allowed. He looked for the fact, and strove to avoid the factitious. And in this way, like many a practitioner who remains known only to his friends and associates, he did his share in the advancement of medicine.

At the meetings of the Charity Hospital Alumni he participated in the discussions and always told us what he saw and heard and felt. He was a man of one opinion, not having one opinion for public statement and another for private uses. He was never in a hurry to speak, and when he did speak he spoke to the point, sensibly and modestly. He was a true disciple of Socrates, for he admitted his ignorance when he did not know. He was a truly self-respecting man, and, taken all in all, a good fellow in the best sense of the word; and not only are his Charity Hospital colleagues losers by his early death, but the public is too, in as far as he was in touch with it as a medical practitioner and a man.

A Charity Hospital Alumnus.

September 23, 1900.

A Too Common Neglect in antiseptic operating-room procedure is the use of instrument trays, irrigators, and tubes which have not been boiled. Boiled instruments in unboiled trays is doubtful antisepsis.—R. N. Joyce.

Society Reports.

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNÆCOLOGISTS.

Proceedings of the Thirteenth Annual Meeting, Held in Louisville, Ky., September 18, 19, and 20, 1900.

First Day—Morning Session.

The association met at the Galt House under the presidency of Dr. Rufus B. Hall, of Cincinnati, Ohio.

Dr. Lewis S. McMurtry, of Louisville, welcomed the association on behalf of the local medical profession.

The address of welcome was responded to by President Hall.

After the election of Fellows, reading of telegrams and letters from absentees, etc., the reading of the papers was begun.

Erroneous Objections to Bilateral Inguinal Cœliotomy and Shortening of the Round Ligaments via the Dilated Internal Inguinal Rings, and its Superior Ultimate Results in Simple and Complicated Aseptic Retroversions of the Uterus.—Dr. A. Goldspohn, of Chicago, read a paper with this title. For a description of the technique of his operation, the writer referred to his previous articles on this subject. He laid stress upon cutting only through the skin and fat, and making the required opening through the aponeurosis, the canal, and the internal ring bluntly. The ring was very readily dilated, sufficiently to admit one, or, if needed, two fingers, and to admit of drawing out the tube and ovary for the exercise of the highest degree of delicate and exact conservative surgery upon them without doing violence to their supports. The wound was closed in four layers à la Bassini. In the second layer the round ligament became placed as in a sandwich between the posterior surface of Poupart's ligament and a good bundle of elastic muscle at each stitch, which made hernia impossible and saved the ligament from strangulation, while it held it firmly enough against Poupart's ligament to secure a broad union. Thus hernia had not followed the writer's operation in fully one hundred and twenty-five cases that he had examined or had reports from. An impending hernia in one case was due to a severe accident. As the internal inguinal ring was just in front of the normal lateral location of the ovary and ampulla of the tube, these organs and the posterior surface of the uterus could be reached by one finger in a one-inch opening here, as well as by two fingers in a two-inch opening in the linea alba midway between the symphysis and the umbilicus, and for the necessary access to the pelvic wall to shorten the proper suspensory ligament of the ovary and tube this small opening served well; while a large median ventral incision and much traumatism of viscera by that route would be needed, and by the vagina it could not be done at all. The round ligaments were always present if the uterus was. In fully one hundred and ninety cases, including seventy-five simple Alexander operations, he had found both ligaments in each case, after his pupilage on about one dozen dead women. But in four patients he traced one from within the pelvis outward. He had never had a death from the operation. But one patient died from a serious renal complication that was not previously discovered, owing to an exchange of samples of urine by a nurse. Thorough shortening of the round ligaments via their natural channels and anchoring forward (not laterally) was the only operation that had been proven, or was likely to be proven, to stand what the writer demanded as the normal standard for all operations of this kind, and had called the "double test of pregnancy," *i.e.*, that it did not embarrass gestation and complicate labor, which was the single test, but also did not permit a recurrence of retroversion of the uterus after one or more subsequent labors. The difficulties in diagnosis as to the presence of pus were no more than proficient gynæcologists would meet successfully, and doubtful cases could be cleared up by ten to fourteen days in bed with warm douches and extensive fomentations. The scars being in the groins, and covered mostly by hair, were not seen like regular laparotomy scars.

The writer published a table of twenty-two cases, fourteen of which were actually adherent cases, and the adnexæ in all cases required exsection of diseased particles from one or both sides. The present position and condition of the patients' organs and their general health was stated after an average observation of fifteen months. He had eight patients that had borne children normally after his operation, and he cited fifty-one cases from other Alexander operators, in all of which, except two, the same was true. Aside from Burrage, the advocates of the more harmless abdominal and vaginal operations for retroversion have not officially adduced one case to offset this collection. They applied only the single test of pregnancy. Their operations did not hold the uterus in normal position after subsequent labor, as a rule, and therefore they were merely temporary or auxiliary relief measures, but not curative procedures.

In the discussion, Dr. Charles G. Cumston, of Boston, said that from his experience in operating both by the abdomen and vagina, as well as from a pathological standpoint, it had always seemed to him that serious lesions of the adnexa, such as the essayist had treated through a bilateral inguinal incision, were usually out of reach, and that these lesions could be dealt with more easily and satisfactorily through a median, a posterior, or anterior vaginal incision. Simple, uncomplicated cases of retroversion were rare. The Alexander operation in the so-called simple cases of retroversion could be greatly improved by an additional operation through the posterior cul-de-sac.

Dr. Edward J. Ill, of Newark, N. J., called attention to the modified operation which was proposed by Dr. H. W. Longyear, of Detroit, at the meeting of the association last year.

Dr. J. Henry Carstens, of Detroit, rarely saw cases of plain, uncomplicated, non-adherent retroverted uteri that required the Alexander operation. The complicated cases of retroversion required some other operative procedure.

Dr. W. E. B. Davis, of Birmingham, Ala., referred to the indications for performing the Alexander operation, and called attention to the class of cases in which it should be performed.

Dr. Frederick Coggeshall, of Boston (by invitation), had performed over a hundred Alexander operations in combination with some other operative procedure. In simple, uncomplicated cases of retroversion of the uterus, the organ could be easily replaced.

Dr. Rufus B. Hall, of Cincinnati, thought that the old operation of anterior fixation or ventro-suspension of the uterus was not so popular as it was a few years since. Soon it would be done only in rare instances. He believed, however, that a modified operation, such as that advocated by the essayist, was based on rational surgical principles, and thought that the author was working in the right direction.

Round Ligament Ventro-Suspension of the Uterus.—Dr. D. Tod Gilliam, of Columbus, Ohio, read a paper with this title. Various devices had been resorted to for restoring and holding in place the retrodisplaced uterus. All of these had been faulty and many absolutely prejudicial. The need of the hour was an operation that would utilize the natural supports of the uterus, that would insure a fair amount of

mobility, that would adapt itself to the various functions of the uterus—pregnancy and parturition—and that would be lasting in its results and withal easy of execution. Profiting by the work of Ferguson along this same line, he had devised an operation which he thought fulfilled all these indications, and, as he believed, solved the problem most satisfactorily.

The steps of the operation were as follows: 1. A median abdominal section was made three or four inches in length and at the usual site between the umbilicus and pubis. 2. The adhesions were broken up and the fundus was brought forward, after which the patient was placed in the Trendelenburg position. 3. The round ligament was seized on one side and brought to the opening. This might be done either by the fingers or by the aid of forceps. 4. A thread was carried under the ligament at a distance of about one and a half inches from the uterus. The free ends of the thread were brought out of the abdomen and secured by clamp forceps. 5. The other round ligament was secured in the same way. 6. The rectus muscle was exposed near the lower end of the incision by retracting its sheath and by rolling it out of its sheath on the tips of two fingers applied to the peritoneal surface under it. 7. A point was selected one inch external to the margin of the incision and something over an inch above the pubis, through which the perforating forceps specially devised for this purpose was thrust into the peritoneal cavity. The two fingers already in the cavity guarded the instrument in its passage and placed the thread which surrounded the ligament within its jaws. 8. The perforating forceps was now withdrawn, after removal of the clamp forceps from the thread, and both thread and ligament were brought up through the perforated wound in the abdomen. 9. While the ligament was held taut, it was fastened into the wound by a to-and-fro catgut suture passed deeply through the ligament and including the tissues on either side. 10. The opposite side was treated in the same manner and the median abdominal incision closed. Rigid observance of all the rules of aseptic surgery was essential to prevent suppuration, and only a small loop of the ligament should be drawn up through the wound.

First Day—Afternoon Session.

A Case of Composite Teratoma of the Ovary.—This was the title of a brief paper by Dr. W. E. B. Davis, of Birmingham, Ala. The author was in doubt as to the nature of the tumor which he presented, notwithstanding the above diagnosis was made by pathologists of high standing

Mrs. N——, aged thirty-four, married, was referred to him by Dr. E. G. Givhan, of Montevallo, May 3d. She was the mother of three children, and had always menstruated regularly, except when pregnant or nursing. The patient noticed a growth in the abdomen two years ago. She had menstruated in January before the growth was noticed, and then missed her periods until March, at which time she menstruated or bled very freely for two weeks. She then missed periods until the following October, with no untoward symptoms except an attack of colic in August. The movements were noticed before August. After October she menstruated regularly until the following January, missing her periods then until October 24, 1899, when a child was born. She had not menstruated since. After the birth of the child at term, the tumor developed quite rapidly, and on May 7, 1900, she was operated upon. The patient was discharged as cured June 9th. The tumor was quite large and had a pedicle nearly two inches in breadth, quite thick, which was attached to the uterus. The fœtus was so large and so well formed that the essayist was of the opinion that there had been an ectopic gestation, with rupture of the gestation sac and the expulsion of its contents into the cavity of a pre-existing ovarian cystoma. From the history of the case, the diagnosis of an old ectopic pregnancy had been made. He was still inclined to that opinion.

Pathological Description: Examination revealed a large, rounded, ovoid mass about the size of an adult head, covered by a moderately thin fibrous capsule. The capsule was continuous on one side with the tumor mass. The weight of the whole tumor was 2,850 gm. Within the capsule were observed numerous sacs of variable size, which were rounded in contour, and were filled with a semi-fluid, gelatino-albuminoid tissue. Lying in one side of the tumor was part of a fœtus. There were numerous bones of a fœtus lying in the capsule. The upper part of the fœtus was embedded in the solid portion of the tumor. This portion of the fœtus was so intimately combined with the tumor that no sharp line of demarcation could be determined, one tissue gradually passing over into the other. There were numerous nodular and teat-like elevations, in some places covered by smooth skin (?), in others by skin (?) provided with fine, brownish, silky hair. Incision of these frequently revealed a whitish, cheesy substance resembling sebaceous secretion. The soft parts of the fœtus were macerated and quite soft. The bones, such as the vertebræ, ribs, tibiæ, and metatarsals, were exposed in many places There were two well-developed scapulæ (right and left), and to the left was attached some slight semblance of an extremity. Lying in a mass of muscular tissue to the left of the vertebral column was a long piece of bone resembling somewhat a humerus. Attached to the lower end and left side of the vertebral column by means of a flattened piece of bone, was an almost perfect lower extremity. The femur was entirely covered by muscle, but the tibia was exposed at its lower end. Some of the phalanges were missing, but the foot was fairly well formed. Careful dissection of the upper part of the fœtus failed to reveal any cranial bones attached to the vertebral column. There were two pieces of jaw-bone (inferior maxillæ) lying in the mass of tissue at this place. They were well shaped, and a dissection of the right one showed rudimentary tooth sacs and a piece of nerve. The laminæ of the vertebræ had not united, so that the spinal canal was not complete, and the spinal cord was seen lying in this position, with nerves arising regularly from each side. The bones lying free within the capsule were two parietal, an occipital, two pieces of frontal abnormally united, several well-formed ribs, and five or six long bones of extremities. Parts of the lungs, liver, stomach, and about 60 cm. of intestine were preserved.

Microscopical Examination: Microscopical examination of sections of tissue selected from all portions of the tumor showed a very complex histological structure. Some portions of the tissue were composed of simple, fully developed adipose tissue, enclosing occasional bands of unstriped muscular tissue, the whole surrounded by fully developed and practically perfect skin. The skin contained sebaceous and sweat glands in considerable quantities, and hair follicles with hairs in position. The sebaceous glands were larger than those found in normal skin. Other portions showed true myxomatous tissue, still others cartilage, and the early stages of osseous development. Sections from the walls of cysts showed the inner surface of them to be lined by almost true skin; the epithelial layers lay internally, lining the cyst, the papillary portion lying externally. Sebaceous and sweat glands occurred in these sections, and frequently they might be seen opening into the cysts. Other cysts were lined by a simple layer of low cubical epithelium, either in uniform arrangement or thrown into folds or villi, sim-

ilar to the formations found in uncomplicated cystic papillomatous adenoma of the ovary. The lining of other cysts was made up in some parts of flat or squamous epithelium, in other parts of columnar or cubical epithelium of the glandular type, and frequently one kind of epithelium passed over into the other. Anatomical diagnosis: Composite teratoma, combined with cystic adenoma of ovary.

The Treatment of Chronic Cystitis in the Female by Curettage of the Bladder and Instillations of Corrosive Sublimate.—Dr. Charles Greene Cumston, of Boston, read a paper with this title. He drew the following conclusions: 1. Sublimate instillations would often produce a very great improvement in the distressing symptoms met with in both tuberculous and non-tuberculous cystitis, such as a diminution in the frequency of micturition, a decrease of the pain, an increase in the capacity of the bladder, and an improvement in the condition of the urine. In some cases a complete cure might be had. 2. When the instillations failed to produce the desired effect, curettage of the bladder was indicated in both tuberculous and non-tuberculous cystitis. 3. In gonorrhœal cystitis instillations of sublimate were very efficacious and rapidly subdued pain. 4. Under favorable circumstances a radical cure of primary tuberculous cystitis might be obtained by curettage when the vesical lesions were localized and the kidneys free from the disease. Curettage per urethram would not allow the surgeon to reach the entire surface of the bladder, so that when the lesions were extensive they should be directly treated by suprapubic cystotomy. 5. Much relief might be afforded to a large number of patients suffering from tuberculosis of the bladder, but who on account of the advanced stage of generalized infection were in no condition to undergo a more radical operation. 6. When cystitis was due to a prolapsus of the genital organs, and when hysteropexy, combined with anterior and posterior colporrhaphy, did not relieve the bladder symptoms, curettage of the bladder, followed by sublimate instillations, was the proper treatment.

Dr. A. Goldspohn did not believe that infiltrations, etc., of the bladder could be recognized by the curette at an early stage of the disease process. With this instrument the operator could not detect beginning ulcerations or papillomatous growths in this organ. The bladder being a membranous organ, curettage of it was entirely different from that of the uterus, in that the operator did not receive the tactile information or intelligence from this instrument in the bladder that he obtained from it in curetting the uterus. Scraping the bladder, therefore, was done largely at random, without any touch sensation to govern the operator as to how little or how much surface he should curette. Under such circumstances it was not rational to assume that the mucous lining of the bladder would be evenly and uniformly curetted. Uneven surfaces or small areas would be left untouched. In the treatment of infectious cystitis, not tuberculous, he had obtained good results from a solution of from one-half to one per cent. of oil of cloves in water.

Dr. J. Henry Carstens agreed with the last speaker that there were certain points in the bladder in the class of cases under consideration that could not be reached by the curette. He had had cases of tuberculous, gonorrhœal, and septic infections of the bladder which had yielded to the judicious application of permanganate of potassium.

Dr. Edwin Ricketts had never tried this method of treating cystitis in the female, but it seemed to him plausible, and he was inclined to try it.

Dr. Rufus B. Hall directed attention to the danger of over-distention of the bladder with injections. Distention of the organ up to the point of causing discomfort to the patient should be the limit of safety.

Dr. James T. Jelks concurred in the statement of Dr. Carstens that permanganate of potassium was an invaluable remedy for infective disease of the bladder, particularly of the gonorrhœal variety. A solution of 1:6,000 was strong enough to begin with, the strength being increased in accordance with the indications of the particular case.

Dr. T. J. Crofford, of Memphis, had performed curettage of the bladder several times. If the inflammatory process was confined to the neck or thereabouts, there was very little difficulty attending the curettage of that area of surface. No inflammatory zones would be left to cause further trouble.

Dr. Goldspohn did not wish to be understood as opposing curettage of the bladder *in toto*, but believed it ought to be done under the guidance of the eye or tactile sense. He called attention to a new urethroscope with an electric-lamp attachment, the latter illuminating the bladder nicely without generating heat.

Dr. Cumston, in closing, referred to the pathology of bladder lesions, and said they were almost always situated in the trigonum: consequently this was the portion of the viscus which the operator should strive to reach. If the whole bladder surface was involved, suprapubic cystotomy was the operation of choice, and curettage in such a case would do very little, if any good. He used the cystoscope in the treatment of this class of cases.

Four Cases of Perforated Gastric Ulcer, with Remarks.—Dr. Henry Howitt, of Guelph, Ontario, read this paper. The first two cases occurred years ago before the operative procedures were commonly known, and had the usual termination, one patient dying within twenty-four hours from the commencement of the illness without having had a single symptom indicating the existence of the trouble. The other two reported by him were of recent date, and the patients were saved by timely operations. In one the operation was devoid of any serious difficulty, but in the other the abdomen contained gas and a large amount of pus; the colon was enormously distended, requiring to be opened and collapsed before the stomach could be reached. There existed also the remains of a ruptured abscess cavity below the transverse portion of larger bowel, the walls of which were formed by it together with the coils of small intestine and omentum. This had its origin probably in a slight leakage which occurred days before the final rupture. The orifice of the ulcer was of sufficient calibre to admit his little finger, and was situated in front close to the pyloric valve. The surrounding parts were so thickened, dense, and nodular as to resemble exactly carcinoma of the pylorus and adjacent part of the stomach. A section nearly two inches in length had to be removed before the ulcer could be closed. The intestines were previously eviscerated to gain the room necessary to reach the part and to expose the pools of pus in the pelvic flanks and other places difficult to reach. The upper portion of the jejunum was anastomosed by means of a Murphy button to the anterior wall of the stomach. Before this was done care was taken to allow for every possible movement without causing tension of the proximal arm of gut. After the anastomosis was completed, the arm of intestine above was stitched to the wall of the stomach an inch or more to the right and a little above the line of the button. This procedure in his opinion overcame the acute angle and its ill-effects. Drainage tubes were inserted through perforations made in the flanks well to the back, and in the lower abdomen close to the pelvis to the outer side of the right rectus muscle. The sutures were all removed, except two in the middle of the wound opposite the umbilicus, on the seventh day. Three hours later the patient had a sneezing-fit, and the wound tore open from the upper angle

to the umbilicus, exposing the situation of the anastomosis, and coils of bowel protruded. It was restitched an hour later without anæsthesia, and no ill-effects followed. The patient made an uneventful recovery, and was now for the first time in eighteen years free from gastric distress.

In the remarks, which were confined chiefly to points which had appeared to him as important when certain conditions were present, he called attention to the danger, in the early stage after the occurrence of perforation, of the medical man being misled by the state of the pulse and temperature until the opportune time had passed, and narrated three instances; two after perforation of the stomach, in which both were to all indications normal, and one after rupture of the spleen, in which the pulse was normal and the temperature subnormal. Attention was drawn to the admissibility of temporary enterotomy and evisceration when the part on which the operation was required lay deep, or when the abdomen contained much septic material. The former was advised by him in all cases in which the intestines were distended with gas or liquid fecal matter. In one patient four separate openings were made without ill-effects. The puncture became minute when the bowel contracted, and was readily closed by a suture or two. He pointed out that the patients were frequently reduced by starvation to a very low ebb before perforation occurred, owing to the irritable condition of the stomach and rectum, the latter from the effects of oft-repeated nutritive enemata, and for obvious reasons constipation was the rule. In order to nourish the patient after operation he advised the introduction, by means of an apparatus similar to that used for decinormal saline injections, of a pint of peptonized milk into the jejunum during the operation, and also, if constipation was a factor, of a suitable saline cathartic into the ascending colon.

Dr. Richard Douglas, of Nashville, Tenn., had had two cases of perforating ulcer of the stomach in which he urged operation, and while preparations were being made to operate on one of them, the patient died. In the other operation was refused. Death ensued some time later. Post-mortem examination in this case revealed a perforating ulcer on the posterior wall of the stomach; while in the other case the ulcer was confined to the lesser curvature.

Dr. James F. W. Ross, of Toronto, called attention to the difficulty attending the diagnosis of gastric ulcer in some cases. He had operated successfully on one case of perforating gastric ulcer. The patient did not know that she had anything seriously the matter with her.

Dr. Charles Greene Cumston mentioned a case in which there was an ulcer of the stomach and one in the vagina, of embolic origin, associated with arteriosclerosis.

Dr. W. E. B. Davis had never operated for ulceration of the stomach attended by perforation. He had encountered two cases which he should have operated upon had the symptoms been sufficiently marked to warrant operative procedure, but they were not, and he did not feel therefore emboldened to undertake it.

Dr. Edwin Ricketts narrated the case of a woman forty-eight years of age, who had had a gastric ulcer for three years. Under rectal alimentation she gained sixty pounds in flesh. Subsequently she committed some indiscretion in diet, was again taken sick, and consulted another physician, who made a diagnosis of cancer of the pylorus. She went from bad to worse, and finally died. Post-mortem examination revealed a perforating gastric ulcer the size of a lead pencil, situated on the anterior surface near the pylorus.

Dr. F. W. McRae, of Atlanta, said that the work of Mayo, of Rochester, Minn., and other surgeons was sufficiently encouraging to justify surgeons in operating on this class of cases.

Dr. A. Vander Veer, of Albany, spoke of two cases of gastric ulcer which ultimately resulted in carcinoma of the pyloric end of the stomach. From the number of cases in which he had done gastro-intestinal anastomosis, he was satisfied that he had had to deal with the cicatrices resulting from gastric ulcers in many instances.

Dr. D. Tod Gilliam believed that whenever an accurate diagnosis of ulcer of the stomach was made, an exploratory operation at least should be made.

First Day—Evening Session.

Some Points Regarding the Surgery of the Gall Bladder.—Dr. A. Vander Veer, of Albany, read a paper with this title. No great reliance was now placed upon jaundice as a positive symptom. Four interesting and instructive cases were reported, and the following conclusions drawn: 1. An early diagnosis of cases was necessary. 2. In suppuration of the bladder with adhesions, a most thorough examination should be made from within by digital exploration and use of the probe for any possible deep-seated calculi. 3. In prolonged operations upon the common duct or hepatic ducts, when adhesions were present and it was difficult to close the incision, after removal of the calculus, drainage through the peritoneal pouch by means of the lumbar stab was advisable. 4. When the patient was suffering seriously from cholæmia, with marked ecchymotic spots over the body, intense itching, and the blood on examination was found in a septic condition, an operation was not to be encouraged. It was too late in the vast majority of cases for the patients to recover. 5. General practitioners as well as the surgeon should place more earnestly before the patient and friends the dangers of repeated attacks of gall-stone irritation resulting in cancer of the ducts, stomach, or liver.

Second Day—Morning Session.

Diagnosis of Ectopic Gestation before Rupture, Based on Eleven Cases.—Dr. James F. Baldwin, of Columbus, Ohio, read a paper on this subject, which consisted of a brief report of six cases of tubal pregnancy which, added to five similar cases previously reported by him, made eleven cases in which he had made a diagnosis of tubal pregnancy and had operated before the occurrence of rupture, his experience having been in direct contradiction to the dictum of Lawson Tait that such an early diagnosis was not possible. His argument was that in a large number of cases such an early diagnosis was entirely feasible and would be made as a routine when the attention of intelligent general practitioners was sufficiently directed to the subject. He said that while there were no pathognomonic symptoms of tubal pregnancy, the following points would usually be found in these cases: The patient gave a history of several years of sterility (many exceptions); she had missed a menstrual period, perhaps two of them (numerous exceptions); she had noticed some unusual pains in the pelvis, which she would probably describe as boring, griping, or colicky in character, these pains being situated usually in the region of an ovary. She had perhaps within a few days of the time of consulting her physician had a more or less irregular hemorrhage; perhaps had discharged pieces of membrane which she supposed indicated an abortion, and consulted her physician with the idea that such was the case, owing to the hemorrhage and the pain and the suspicion of an existing pregnancy. Possibly, however, there had been no suspicion of a pregnancy, as the woman had ac-

cepted her sterility as incurable and had dismissed from her mind such a possibility. On making a vaginal examination, if the conditions were at all favorable, the examiner would find upon one side or the other of the uterus, or back of it, a fusiform, quite well-defined cystic tumor, about the size of a pullet's egg or a little larger. This tumor would probably be quite tender on pressure, quite symmetrical in outline, and usually distinctly pulsating. When such a tumor was found in a woman in whom there was reasonable grounds to suspect a pregnancy; when the uterus at the same time was found somewhat enlarged, and having the feel of pregnancy, but not enlarged so much as one would expect in a pregnancy of so long continuance as the history indicated, a presumptive diagnosis of tubal pregnancy was warranted, and the matter of an operation should be carefully and without delay considered. To render the early diagnosis of ectopic pregnancy possible, it was necessary for physicians to learn to suspect it, and to examine patients with that suspicion in mind. The physician who, without making any examination, told all middle-aged women who came to him complaining of irregular hemorrhages that they were merely having the change of life, would not be likely to make an early diagnosis of cancer of the uterus, and he would probably tell patients who came to him with symptoms of ectopic pregnancy that they were merely threatened with a miscarriage. He would make no further investigations, and would hence uniformly fail to make a diagnosis. The physician, however, who, having in mind the possibility of an ectopic pregnancy, throughly examined all patients whose history and symptoms pointed to this condition, would in a large proportion of cases make a correct diagnosis, and by prompt intervention would achieve a signal triumph for himself and his profession.

Dr. Edward J. Ill asked as to the nature of the contents of the tube, to which Dr. Baldwin replied that in nearly all of the cases there were some blood clots pure and simple.

Dr. Charles A. L. Reed said that to make a diagnosis of tubal pregnancy before the time of rupture, it was necessary to have the patient under observation constantly for a considerable length of time. He had encountered such a case about seven years ago, the details of which were narrated.

Dr. L. H. Laidley said the only diagnosis of ectopic pregnancy he had ever made was in a case of cancer of the uterus when there was no rupture. He did not suspect the existence of it until he had removed the tubes and had found indications of a developing fœtus within the tubes.

Dr. Zinke, of Cincinnati, thought the diagnosis of ectopic gestation was easy in some cases if the gynæcologist had certain symptoms to guide him, namely, loss of blood, either scanty or profuse, attended with pain, and a tumor, pulsating in character, found on one or the other side of the uterus. In other instances, however, the diagnosis was very obscure, particularly in those cases in which the ectopic gestation was complicated with a normal pregnancy. Such a case was narrated.

Dr. D. Tod Gilliam said that if the gynæcologist could diagnosticate most cases of ectopic gestation before rupture had taken place, it would prove a great boon to womankind. A distinction between tubal pregnancy and inflammatory conditions should always be borne in mind

Dr. A. Goldspohn said he had made a diagnosis of extra-uterine pregnancy in five cases.

Dr. J. Henry Carstens did not think cases of extra-uterine pregnancy were as common as the profession generally supposed. The average general practitioner with a good practice observed but very few such cases in a lifetime. He spoke of the difficulty in diagnosis, and said that when this condition was expected and operated for, something else was found.

The Surgical Treatment of Uterine Displacements was the title of a paper read by Dr. Charles A. L. Reed, of Cincinnati, Ohio. Attention was called to a couple of modifications of technique in the management of a class of cases that was happily becoming less and less perplexing. It was not the author's purpose to discuss the relative merits of Alexander's and Mann's operations, or to consider the ingenious technique of Ferguson. In a majority of all cases of retrodisplacements that demanded operation at all, the author believed that the intraperitoneal shortening of the round ligaments was the operation of choice. It had been his habit during a number of years to effect this by making a letter-of-S fold in the ligaments and stitching them thus folded to the parietal peritoneum along the line of Poupart's ligament. This method had yielded him better results than any which he had previously tried. He had, however, become convinced that the parietal fixation of the folded ligament was not necessary for the purpose of holding the uterus in its normal position, and that the technique devised by Mann was all that was required to accomplish this object. His application of this technique differed a little from that originally adopted by Mann, the modifications being those of convenience rather than of necessity. These modifications are here given in the language of the author: "In seizing the round ligament with hæmostatic forceps for the purpose of folding it upon itself, the tissues are frequently wounded. While the accident is not a serious one, it is certainly not desirable. The use of two hæmostatic forceps for the purpose of effecting the fold makes the services of two hands of an assistant necessary. To obviate these objections, which though of minor importance are still objections, I have devised a forceps with four flat approximating prongs, the whole being an inch across. The prongs of the opposing blades approximate with sufficient force to hold the ligament, but not enough to induce tissue necrosis; while, when approximated, they are far enough apart to permit the passage of a medium-sized needle between them. The ligament, brought up into the field of operation on the finger, is seized in its middle third by this instrument, which is then turned one-half around, thus effecting by a simple twist of the wrist the desired shortening of the ligament. It is then held in this position until all of the sutures are applied. These are inserted as follows: one interrupted, one fixing the loop of ligament to the cornua of the uterus; a similar suture is utilized to fix the outer fold of the ligament; a continuous suture is then passed between the prongs of the fixation forceps, its ends being obliquely tied after the instrument is withdrawn. A pathological condition that often exists in cases of long-standing flexions and the persistence of which militates against the success of any fixation operation, consists in an atrophy of the concave wall and an hypertrophy of the convex wall at the point of flexure. In many cases, particularly when associated with diffuse fibrosis, the elongated and hypertrophied wall offers a persistent resistance to the maintenance of the normal axis of the organ. To overcome this I have, for some time, removed a cuneiform segment from the hypertrophied wall, an operation which Thiriar calls cuneo-hysterectomy, and which is applicable in either anterior or posterior flexions. To do this the patient is placed in the Trendelenburg position. All adhesions between the uterus and bladder, or between the uterus and other organs, are carefully broken up, the rents in the serosa that may be induced thereby being carefully stitched. The uterus is then brought toward the incision by gentle but firm traction, and an ellipse

of tissue about 1 cm. wide and having a length corresponding to the breadth of the organ is removed from the convex side at the site of flexure. Care must be taken not to carry this dissection into the cavity of the uterus nor to wound either the circular artery or the anastomosing branches of the uterine artery. Should the latter accident occur, it is best controlled by ligatures *en masse* passed deeply into the uterine tissue at either end of the yet gaping ellipse. Retraction of the vessels generally prevents their isolation and closure by direct ligature, which, when practicable, is always the preferable method. After all hemorrhage, except mere capillary oozing, is controlled, the margins of the ellipse should be carefully approximated and closed by a continuous animal suture passed deep into the matrix. It may be well to fortify the continuous suture with two or three interrupted ones of the same material. The uterus is then dropped back, and after pausing a moment to make sure of complete hæmostasis, the abdomen is closed without drainage. A further modification of this operation, that I have practised with satisfaction in anteflexion, consists in stitching a reef of the posterior folds of the broad ligament to either side of the posterior surface of the uterus. I have been able by these combined methods to relieve the most distressing and persistent symptoms, vesical, uterine, ovarian, and neurotic, due to otherwise intractable anteflexion of the womb."

Fibroma of the Ovary, and Exhibited Specimens.—Dr. L. H. Laidley, of St. Louis, Mo., read this paper. After giving the pathology of fibromata of this organ, the author reported the following case:

Mrs. H——, aged twenty-nine years, married, usually enjoyed good health, with the exception of almost complete deafness due to a specific disease, for which she was treated some fifteen years ago. She became pregnant, and was delivered of a healthy child about two months before the removal of the tumor. She had noticed a tumor in the region of the left ovary about two years ago; it was hard and slightly movable, and continued to grow to the size of two fists. In the development of pregnancy it was pressed upward on a line with the umbilicus and could readily be felt in her left side. There was no pain or discomfort with its presence up to the tenth day after her delivery. She had a favorable "getting-up," when on the fifteenth day she had fever with pains, causing her again to take to her bed. These continued until he saw her two months later. Upon examination he found the lungs, heart, and abdominal viscera in normal condition. There could be readily felt and seen a hard, immovable tumor in the left umbilical region, with considerable ascitic fluid in the cavity. On January 20th an abdominal section was made, revealing a solid tumor adherent to the anterior wall of the abdomen, which was detached. Posteriorly the folds of the bowel were adherent to that portion, which were also dissected off and the tumor was freed. It was kidney-shaped, hard, with short pedicle, one inch in diameter by two inches in length; this was ligated and the tumor removed. When the ligature was tied it readily cut through its peritoneal covering, but secured the stump from hemorrhage. On examination of the remaining organs, the stump of the pedicle occupied the location of the ovary; the tube remained distinct and separate from the tumor; the opposite side showed a healthy tube and ovary; there was considerable loss of blood from the surface hemorrhage following the operation, but with that exception there was no difficulty encountered. The patient made an uninterrupted recovery. The tumor weighed thirty-two ounces, and measured six by five by three inches. A histological report accompanied the recital of the case.

Dr. Laidley also reported an interesting case of hernia or diverticulum of the chorion.

Diffuse Non-Malignant Papilloma of the Vulva.—Dr. Edward J. Ill, of Newark, N. J., read this paper and showed a specimen which he had removed from a patient sixty-eight years of age. The growth had been of over three years' standing. The inner surfaces of the vulva were thickened, at some places appearing horn-like, white, and smooth; at other places there were heavy papillæ which rose considerably above the surrounding tissue and were from 3 mm. to 15 mm. in diameter at their base. The disease extended from the beginning of the vulva above down to the posterior commissure. It covered the whole vestibule except the tissue immediately surrounding the external meatus of the urethra, and was well defined, but stopped at the vaginal mucous membrane. The vulva as a whole stood out far beyond its normal elevation. The whole vulva was excised. The structure of the tumor corresponded with that usually found in papillomata of the skin. A second case was spoken of by the writer. These two cases comprised all the experience he had had.

President's Address.—This was delivered by Dr. Rufus B. Hall, of Cincinnati, who selected for his subject "The Education of the Laity upon Sexual Matters; When Shall They be Taught and to What Extent? The family physician should be the educator of the people in sexual matters, and when he got the indorsement, and was sustained in his position by the specialist, his influence would be greatly strengthened and widened. The author advised that during the last year in High School, in every school in the land, a text-book be employed embracing embryology, hygiene, anatomy, and physiology, including sexual physiology, and that these subjects be taught to every student, both male and female. He believed that this could be accomplished without shocking the morals of the most fastidious individual, by dividing the classes so as to separate the sexes. A female teacher should instruct the girls, and a male teacher the boys. This was the very time in life when individuals should be taught to know the functions with which Providence had endowed them, and how to care for their bodies as well as their minds. It would be a revelation to them to know that the sexual organs in animals as well as the human race were among the first centres to be formed, and could be recognized as such early in intrauterine life. When the laity became educated upon this subject as they should be, and understood the meaning of pelvic inflammation in young wives as gynæcologists understood it, the parents and guardians of young girls would realize that they owed them a duty before consenting to their marriage.

Second Day—Afternoon Session.

Private Hospitals and their Management.—This was the title of a paper by Dr. Joseph Price, of Philadelphia. The well-organized private hospital, managed by such distinguished men as Marion Sims, T. G. Thomas, Thomas Addis Emmet, William Goodell, Stone, of New Orleans, and a few institutions of the present time doing the best work, offered advantages that were not given by the schools or the political hospitals. The political hospital was not the only corrupt institution; a few of the well-endowed general hospitals, managed and handed down in families to the third, fourth, and even the fifth generations, were the most dangerous institutions in the medical profession. It was always a misfortune to an endowed charity or public hospital for a family to be in full possession of the funds or endowments, in that this resulted in impairing or destroying its usefulness. No one had ever to the speaker's personal knowledge made money and accumulated wealth out of a private sanatorium. He might do so out of the fees, but never out

of the board, care, and nursing of patients. The board of patients rarely paid five per cent. on the money invested. A good number of these institutions had been financial failures and had closed. Private hospitals gave the operator the best opportunity for doing good work. In well-managed private institutions the patient had one or more attendants with well-regulated relays. In public institutions the speaker rarely found a nurse in large wards, the only attendants about the patients being a convalescent patient or an old pelican of an attendant. Professional care, one or many visits daily, favored a speedy convalescence. The early and late assurance that a patient was doing nicely did a world of good. Fresh beds, and the numerous little attentions from young, intelligent nurses, favored comfort and confidence. It was surprising how much more cheerful patients were in private hospitals than in general, public, or school institutions. The surroundings of general hospitals were generally depressing. Patients were eager or impatient to get home prematurely. In a well-managed private institution they were easily controlled and were willing to remain until they were fully convalescent. Hurrying patients out of general hospitals, one, two, or three weeks after serious operations, resulted in accidents and complications, post-operative sequelæ, difficult to correct. In private institutions there was added a well-directed rest-cure treatment, which gave pleasing results.

Post-Rectal or Pre-Sacral Growths.—Dr. James F. W. Ross, of Toronto, presented this paper, in which he reported four cases of post-rectal tumors, excepting the osteomata. He discussed benign and malignant growths in this region; also their etiology, symptomatology, diagnosis, prognosis, and treatment. No novice should undertake the removal of a post-rectal growth. It could be done only by one who had become familiar with pelvic surgery, and who was fully master of the situation. The operator must be full of resource and should be rapid in his movements. In making his incision into the abdominal wall, he should always remember that it should be made high up and enlarged downward after the position of the bladder had been ascertained. The author had had no experience with the removal of such post-rectal growths by enucleation from above. He was well aware that many thoughtful, prudent, and daring surgeons did not hesitate to close the abdomen when this condition was met with. What should the technique of such an operation be? Should the meso-rectum be incised close to or far away from the bowel? Should not the incision always be parallel to the vessels and not across them? How was the surgeon accurately to determine the situation of the ureter, and, when discovered, how could he avoid it? How could he best guard against injury to the large vessels? In dealing with branchial cysts in the neck the speaker had followed them almost to the spine, but had then left the deep portion of the cyst wall, if it could be called a wall. It seemed to him that he would have been forced to deal with the last case he reported of pre-sacral cyst in exactly the same manner, because the periosteum and so-called cyst wall were so intimately connected. It would not be wise to drain such a cavity into the peritoneal cavity, but would be more prudent to attack such cysts through the post-anal tissues, perhaps with the removal of the coccyx. The solid tumors should always be attacked from the front.

Third Day—Morning Session.

The Ligature and the Value of Dry Sterilized Catgut.—By Dr. J. Henry Carstens, of Detroit, Mich. The author described a modification of the Boeckman method of preparing catgut. The ligatures were prepared in the following manner: Catgut was put in ether for a few days or a week until the fat was all removed, and then cut in strips eighteen or twenty inches long. Three of these were wrapped in fine tissue paper, then placed in a small envelope. The latter was closed, placed in a Boeckman sterilizer, and subjected to dry heat for three hours. A thermometer was kept in the apparatus, so that the heat was at least 300°. At the expiration of that time the heat was shut off, and the ligatures remained in the sterilizer without disturbance for twelve to eighteen hours, which gave any spores that might be present an opportunity to develop. Then heat was again used, and the ligatures were subjected to another 300°. They were now sterile. They were put in an envelope and could be carried that way in a satchel. When ready for use the end of the envelope could be torn off and the ligature, with the tissue paper, dropped into alcohol, the tissue paper removed, and the ligature could be threaded and used. These ligatures were not slippery or greasy, as was the catgut prepared with different oils. The following points were emphasized: All buried sutures ought to be absorbable, and absolutely sterile. Chemicalized sutures were no more sterile than plain sutures. A chemicalized suture was harder and remained longer in the tissues. This latter was a disadvantage. If in a special case it was desirable that a suture should remain longer, dry sterilized kangaroo tendon could be used.

Some Contraindications to the Intraperitoneal Use of Decinormal Salt Solution after Abdominal Section.—Dr. Frank F. Simpson, of Pittsburg, Pa., read a paper dealing with this subject.

Simple Methods in Pelvic Surgery was the title of a paper read by Dr. John B. Deaver, of Philadelphia. Simplicity was the *sine qua non* of good surgery. It meant safety, surety, confidence, neatness, and great saving of time, which was an essential factor in the success of many operations. The abdominal route was by far the more rational, and therefore the best method of approaching an operation on the pelvic organs in the majority of cases, and offered several advantages that rendered it preferable to the vaginal. It was simpler of performance. It was safer, as the surgeon could avoid distributing infection when infected areas were present. It reduced the danger of general peritonitis by the use of gauze packing. It rendered injuries to the bowel, ureters, important blood-vessels, etc., less likely. It minimized the danger of hemorrhage. It aided generally by the facility offered for inspection. Through the abdominal incision the surgeon was able to open the belly to the proximal side of the infected area, when, by the proper disposition of sterile gauze sheets practically all risk of peritoneal contamination was done away with. It enabled the surgeon to operate with a very few instruments. Radical operations per vaginam were, with few exceptions, the author thought, to be discountenanced, for several good and sound reasons: (1) The limited area for manipulation; (2) the impossibility of inspection without destruction and removal of the uterus, which should not be removed except for good and sufficient disease of that organ itself; (3) the marked increased liability to hemorrhage, both primary and secondary; (4) increased danger of injuring ureters, bowel, bladder, and large blood-vessels; (5) danger of doing incomplete surgery; (6) inability to repair satisfactorily injuries to bowel or bladder, etc.; (7) inability to deal safely with an inflammatory mass which involved the vermiform appendix.

The Treatment of Fibroids in the Non-Pregnant Uterus.—A paper on this subject was read by Dr. E. F. Fish, of Milwaukee, Wis. The author discussed the advisability of operating in all cases of fibroids of the uterus as soon as discovered, and left it an open question. He emphasized the necessity of radical interference whenever the tumor or tumors were pro-

ductive of symptoms—pain, hemorrhage, pressure, constitutional impairment, unless there be existing disease, such as nephritis, diabetes, tuberculosis, etc. Of radical treatment, he thought that myomectomy was the operation of choice, whether subserous, interstitial, or subcutaneous, if the tumor was single and could be enucleated without loss of tissue and the cavity closed and covered with peritoneum. When several tumors existed, the judgment of the operator came into play. Many nodules meant many foci, and the author opposed myomectomy on the ground that some of these might not be discovered, and later might develop and demand another operation. He thought, too, that under such circumstances the condition was a general one extending to the tubes and ovaries, and this condition might, and likely would, call for future operation. The vaginal route was favored for small tumors, the abdominal for large ones. Hysterectomy was favored when the tumor involved so much uterine tissue that a proper closing of the tumor cavity was not possible, when the organ was studded with small tumors or nodes, when coexisting pelvic disease was present, when the growth was degenerating, when there were adhesions, when the tubes and ovaries were involved to such an extent that they must be sacrified, when the disease was no longer local, or when the change of life had occurred. He favored supravaginal amputation, leaving the cervix when sound, and panhysterectomy when the cervix was lacerated or diseased. He left the ovaries if sound, or if only one was sound he left that, or if only part of one he left that. He believed in ignipuncture for small pea-like cysts, and left the ovary. He was convinced that this plan modified the nervous symptoms which usually followed complete removal.

Palliative treatment was discussed, the author paying most attention to curettage and electricity, and he briefly touched on salpingo-oöphorectomy, ligation of the uterine artery, organotherapy, medical treatment, and natural cures. He concluded that myomectomy was the operation of choice (1) when the tumor was pedunculated; (2) when single, whether subserous, interstitial, or subcutaneous, and could be enucleated without loss of uterine tissue, and the tumor cavity closed and covered with peritoneum; (3) when the desire for an heir outweighed all other considerations. Hysterectomy was indicated (1) when the tumor involved so much of the uterus that a cavity too large to be properly closed and covered with peritoneum would follow its removal; (2) when several tumors existed, especially little nodules; (3) when the adnexæ were diseased to such an extent that they must be sacrificed; (4) when the disease had ceased to be local; (5) when hemorrhage, pressure, or pain was a persistent symptom; (6) whenever malignancy was suspected, or the tumor was of rapid growth; (7) after the change of life. Palliative treatment was indicated when the patient was much reduced from loss of blood, as a prelude to rational cure; when the existence of chronic nephritis, diabetes, tuberculosis, or other constitutional disease forbade rational cure; and when the patient was past forty years of age, the tumor small, the main annoyance hemorrhage, and she was desirous of awaiting the effect of the menopause.

Acute Senile Endometritis.—Dr. L. H. Dunning, of Indianapolis, Ind., read a paper with this title, it being the second written by him upon this subject, and in which he reaffirmed his belief that it was a distinct lesion that had not heretofore been adequately described. Since his previous paper he had encountered three more cases, two of which were attended by sanguino-purulent discharges from the uterus, and one in which there was a large pelvic abscess. The inflammation tended to spread beyond the endometrium into the Fallopian tubes, ovaries, and pelvic peritoneum, resulting in much suffering and ill health, and not infrequently leading to so serious involvement of these structures as to demand operative procedures, such as extirpation of the uterus and appendages, or vaginal incision and drainage of a pelvic abscess. The chief cause of the lesion was infection. It was not definitely self-limited, but tended to become chronic and to lead to marked degenerative changes within the uterus. The treatment recommended was, in cases in which the appendages were not involved, dilatation, curettage, the application of a mild caustic, and prolonged drainage. When the uterine appendages were involved in the inflammatory process, extirpation of the uterus and appendages was advocated.

Tubo-Ovarian Abscess and How to Deal with It.—A paper on this subject was read by Dr. Edwin Ricketts, of Cincinnati, Ohio. Tubo-ovarian abscess was frequently caused by the proximity of the ovary to an infected Fallopian tube. The disease might be complicated by normal or ectopic pregnancy, intestinal, vaginal, or vesical fistulæ, and by appendicitis. In the dormant stage the author operated by the abdominal route; in the acute stage he explored by the abdominal route, and then decided between completing the operation in one or two sittings. Following abortion or delivery at full term, vaginal drainage in his opinion often put the patient in better shape for an abdominal section later on.

Observations Respecting Malignant Disease of the Pelvic Organs.—By Dr. Augustus P. Clarke, of Cambridge, Mass. Cancer may have its starting-point in a lacerated cervix uteri; but its seat of development was usually in the epithelium. Its occurrence not infrequently took place after the patient had become a multipara and before she had become of advanced age. The exposure of the mucous membrane to continued or repeated irritation hastened its onset. Cancer of the uterine body had had its origin from endometritis and from its allied conditions. The disease might be induced or intensified by inflammation of the utricular glands of the uterus and by the effects of external pressure. A sarcomatous condition might result from the same cause. Cancer of the broad ligament, as also that of the ureter, had been observed as the result of extension from the uterine cervix. The meatus urinarius had been noticed as an original seat of cancer. In such cases vesical and urethral disturbances had been known to antedate the appearance of the malignant change. Cancer of the ovary, or of other portions of the adnexæ, might occur as secondary to a primary point of invasion. The route of transmission was usually along the course of neighboring lymphatics, or along the epithelial cells of the ducts of such open channels of communication. The fact that cancer cells might so readily invade the epithelium of newly formed growths containing endothelium showed the importance of taking measures for their early removal before degenerative changes had extensively occurred. The morbid development undoubtedly arose at times by abnormal proliferation of the epithelium from its basic point of origin to the deeper structures within. The majority of cases of cancer occurring in the bladder were secondary to involvement of the cervical portion of the uterus. The cases which called for special consideration were those of the villous type. Curettage and the employment of the galvano-cautery afforded the best means of relief. In those cases of rectal cancer in which the sphincter ani was not invaded, excision of a portion of the rectum and the removal of the coccyx and the lower section of the sacrum could sometimes be advantageously done. The use of the Murphy button in such cases was of service. The only effectual radical method of treatment was by excision. Partial removal of the uterus on account of extensive invasion by malignant

disease would not suffice. The fact that uterine or pelvic fibroids and fibromyomata might take on malignant transformation was coming more and more to be recognized. The necessity of watching closely for changes that might be assumed became obvious. Both the round and the spindle-shaped cell sarcomata might originate in benign fibroids. The total excision of such neoplasms in their earliest stages would afford the most satisfactory results.

Difficult and Obscure Pus Cases in Pelvic Surgery in Women.—By Dr. Walter B. Chase, of Brooklyn, N. Y. The author first considered the etiology of these cases, classing gonorrhœa as the most frequent cause, closely followed by miscarriage and labor at full term, these usually following some infection from without. Among the causes from within were considered those following the rupture of an ectopic tube, hæmatoma, malignant or tuberculous disease, and others less frequent in occurrence. The question of time should be considered in the diagnosis, but the great mainstay was thorough and systematic bimanual and rectal examination. The author called attention to the fact that fluctuation might be due to cystic growths, recent hæmatomas, amyloid degeneration, etc., as well as to pus. Pain and fever, or their absence, went far to clear up diagnosis in many a case, but the fever due to malignancy must not be confused with that due to septic causes. Appendicitis and pus tubes might cause difficulty in differentiation. The rule that pus in the pelvic cavity must be evacuated was general, though not universal. The manner and route of its evacuation were thoroughly discussed. Drainage was next considered, the author taking up the direction and the material, usually preferring plain or iodoform gauze, and at the same time considering irrigation, for which he generally used decinormal salt solution. Multiple abscesses were considered next with their management. The serious cases in which pus existed free in the pelvic cavity were taken up, and among other things he stated that sentiment should be allowed no weight in their treatment. Another embarrassment to the operator was the failure of the public to discriminate as to the cause of fatality, in many of which cases the operator had nothing to do with the mortality. In closing, he cited several pertinent cases, in one of which two abscesses were caused by the escape of the bacillus coli communis, evidently from a denuded spot on the serous covering of the bowel.

The following officers were elected for the ensuing year: *President*, Dr. W. E. B. Davis, of Birmingham, Ala.; *First Vice-President*, Dr. Edwin Walker, of Evansville, Ind.; *Second Vice-President*, Dr. A. Goldspohn, of Chicago, Ill.; *Secretary*, Dr. William Warren Potter, of Buffalo, N. Y., re-elected; *Treasurer*, Dr. X. O. Werder, of Pittsburg, Pa., re-elected.

Cleveland, Ohio, was selected as the place for holding the next annual meeting; time, the second Tuesday in September, 1901.

No Danger of Overcrowding.—Mr. M. G. Mulhall, the well-known British statistician, says that there will be plenty of room on the earth to support human life comfortably for many centuries to come. The area of the United States, excluding Alaska, is just three million square miles; the average density of the New England States is seventy-one inhabitants to the square mile, so that judging from these figures it may be said that this country could easily support two hundred and ten million, or three times its present population. In the mean time other vast fields are opening. Canada, Brazil, Spanish America, Africa, and Australia can each find room for hordes of immigrants.

Medical Items.

Chronic Constipation.—Cheadle says that the treatment of chronic constipation is a subject of considerable importance and deserves more attention than it usually receives. It lies for the most part outside hospital practice. It is a frequent source of trouble to the practitioner and sometimes of discredit to him. In the first place, if treatment is to be successful it must comprise something more scientific and comprehensive than the mere administration of occasional aperients. It is not enough to open the canal when blocked or sweep it clear of accumulations which have lodged there. The essential point is to establish, if possible, such a habit of daily evacuation that accumulation of noxious waste and its evil consequences may not recur, to modify the condition permanently if the age and condition of the patient render such a consummation possible. In order to do this the causes which give rise to it must be thoroughly understood, removed, neutralized, or compensated.

Some of the Properties of Oysters.—Oysters have for centuries been much esteemed by medical men as being very nutritious and easy of digestion, but both these properties are much diminished when not taken in their raw state. It may not be generally known that the fluid which surrounds the oyster bears a closer analogy to the gastric secretion than anything else in nature. In addition to the solvent properties of this fluid it is not without its nutritive properties. We have of late devoted considerable attention both to the substance and secretion therefrom, and find that in a given weight of the latter and the same of the oyster the fluid yields only forty per cent. less of animal gluten or jelly than the fish. Consequently all persons who are accustomed to eat oysters should be ever mindful that as little as possible of the juice should be lost. When oysters are eaten stewed or scalloped, the two properties, as before stated, are much diminished; consequently they ought never to be taken by invalids except in their raw state.—*Sanitary Record.*

Mushrooms.—There are more than six thousand varieties of mushrooms, of which three hundred are edible. Many of the noxious species produce intoxication. The convicts of Siberia use for this purpose a mushroom termed the fly-agaric, which is rolled into a ball and swallowed whole. Its effects are not unlike those produced by opium. Taken in light doses the person is affected as by the inhalation of laughing gas. There are six families of fungi, to the first or highest of which belong mushrooms and toadstools. The minutest forms of fungus have been found in places where no one would expect to find them—for example in the interior of apparently perfectly sound hazelnuts, in the cavities in tomatoes with unbroken skins, in the inside of polished Bonduc nuts, which are almost as hard as metal, and even in the bubbles within pieces of amber. They are independent of light even for growth. In some cases, offering a decided contrast to the usual plant requirements, light appears positively harmful to the fungus.—*Answers.*

Plague in Glasgow.—The British journals, as was perhaps only natural, endeavored first to throw doubt on the truth of the announcement that the Oriental pest had broken out in Glasgow, and then, when it had been clearly proved that unfortunately such was the case, took pains to show that there was little or no cause for alarm. A prominent weekly paper discusses the question as follows: "There are two great allies of the fell disease, without which it never makes and never can make much progress. Those are dirt and

funk. Modern sanitary science is quite capable of dealing with the plague, and secure in the knowledge of this central fact we may cheerfully defy the enemy's other chief supporter—the abject terror which predisposes its victims to catch any infectious disease which may be going about, and which is really responsible for half the mortality in most epidemics. When indeed one remembers that the plague must be seaborne, and that the greater portion of the world's carrying trade is in English hands, the wonder is not that the infection should have reached us at last, but that it did not effect a landing at one or more of our ports many months ago. The fact that it should not have done so should suffice to convince the most nervous among us that we are in no danger of an epidemic of the 'Black Death' of the Middle Ages or the pestilence whose ravages in seventeenth-century London were so graphically described by Daniel Defoe. Let us only keep clean and cool, and the doctors may call the new malady by any name they please." This is very good reasoning so far as it goes, and especially with regard to the evil effects of panic, but at the same time it should be borne in mind that parts of Glasgow are woefully overcrowded and distressingly dirty. If the health authorities of Sydney did not succeed in stamping out the plague in that city for many months and until many lives had been lost, then the argument may be made that in all probability the health authorities of Glasgow, which is no cleaner than Sydney, will have quite as much difficulty in abolishing the disease from its borders.

Women Longer-Lived than Men.—An English weekly magazine says that statistics show that women live longer than men. For instance, in Germany only 413 out of 1,000 males reach the age of fifty years, while more than 500 out of 1,000 females reach that age. In the United States there are 2,583 female to 1,398 male centenarians. In France, of 10 centenarians 7 are women and only 3 men. In the rest of Europe, of 21 centenarians 16 are women.

Yawning is Healthy.—A German scientist has discovered that yawning is a healthy pastime. It is wholesome like oatmeal and brown bread. Yawning, it is said, stretches the muscles, maybe, or the tendons of the head, sends the blood to the jaws, and sharpens appetite and intellect. It is a cheap remedy, accessible to young and old, rich and poor, and if it is as efficacious as our Teuton says, health is surely within the reach of every one.—*The London People.*

The Origin of the Glasgow Plague.—Surgeon-General Wyman has received a report from Assistant Surgeon Thomas of the Marine-Hospital service, in charge of the plague inspection work at Glasgow, detailing the history of the outbreak there. The report states that all the cases now under surveillance are to be traced to a wake held over a woman who died about August 21st. She lived in a crowded tenement quarter, some distance from the shipping, and no connection can be traced between her sickness and any infected ship except that her husband was at work on the docks. The disease in the early cases was of the pneumonic form, and the death of this woman was certified as pneumonia, and there were a number of other cases of supposed pneumonia among those who had attended the wake or had been thrown into contact with the woman. On August 25th a child died, and on the 27th his mother and two brothers were taken to the hospital. One of the brothers died, and his death was certified as bubonic plague. Cultures of the plague bacillus were made from his organs, but the inoculation experiments are not yet complete. As soon as a suspicion of plague arose all persons known to have been in contact with the cases mentioned were removed to new quarters, were bathed, and their clothing was disinfected. A few cases have been sent to the hospital from this contingent, which at present amounts to something over fifty. All the cases in the hospital at the time of Dr. Thomas' report were of the bubonic form. Careful inquiry does not show that there has been any unusual mortality among the rats in Glasgow, but war has nevertheless been declared against them, and rat-catchers are busy capturing and killing them.

The Right of a Hospital to Discriminate in the Reception of Patients.—It is stated in *The Sun* that a medical controversy, growing out of the custom of club practice, is about to be carried into the courts of Massachusetts at Springfield. The Hampden County Medical Association has expressed its disapproval of this practice, insisting that no special arrangements for charging less than the ordinary fees should be made with medical clubs, lodges, and other benevolent organizations, but the societies have found no difficulty in securing the services of physicians who agreed to treat their members for a stipulated sum per annum. A patient who was sent by one of these contract physicians to the Mercy Hospital in Springfield was refused admission to that institution unless the doctor in attendance withdrew from the case, which he finally consented to do for the sake of the patient, who required treatment which could be afforded only at a hospital. A suit will now be brought to ascertain whether the hospital staff could lawfully take this action under its charter, which provides that all patients shall be treated there who are brought to the institution by reputable physicians.

The Fatal Bloom on the Fruit.—Schnirer reports the results of an examination showing the danger of eating fruit without first washing it. While at work one day in Weichselbaum's laboratory he sent for some grapes to eat. The fruit had been kept for some time in a basket outside the laboratory, and was covered with dust, so that the water in which it was washed was black. On examining this, Schnirer reflected that, inasmuch as the neighboring street was traversed by consumptive patients going to the clinic, the dust might contain tubercle bacilli, and to settle this he injected into three guinea-pigs 10 c.c. of the water in which the grapes had been washed. One animal died in two days, the two others died on the forty-eighth and fifty-eighth days respectively, the latter presenting marked tuberculous lesions, especially at the place of injection. The water in which the grapes had been washed was taken from the faucet, and the glass containing it had been sterilized; neither the boy who had brought the grapes, nor the merchant who had sold them, was consumptive. The cause of infection was beyond doubt the dust on the grapes. This danger was recognized long ago by Pasteur. One day at a large family dinner he called the attention of those present to the danger of imbibing germs while eating fruit, and to impress the necessity of caution upon his hearers washed his bunch of grapes in a glass of water. After he had finished the grapes and had forgotten his little speech, being thirsty, he drank from the glass in which the grapes had been washed, thereby arousing much merriment among the irreverent youngsters present.

Mosquitos.—The Department of Agriculture is about to issue a bulletin prepared by Entomologist L. O. Howard on the mosquitos of the United States. It discusses their structure and biology and indicates the difference in all stages of existence between the kind of mosquitos that transmit malaria (Anopheles) and those that do not (Culex), and also discusses the subject of remedies. Among other things the bulletin

says that since the opening up of the gold-fields in Alaska and the great influx of miners and traders, knowledge of the abundance and ferocity of the Alaskan mosquito has become widespread, and government surveying parties in starting for Alaska for their summer's work are in the habit of consulting the department for mosquito-bite remedies. The bulletin says there is a constant carriage inland from the marshy coast of very many mosquitos, the railway trains seeming to be the most important mode of conveyance. Many of the cars contain mosquitos by the hundreds. In this way even mountain resorts will get their supply of mosquitos, and with the improvement of railway service and the increase in the number of through cars the danger is constantly increasing. Only about thirty of the two hundred and fifty known varieties of mosquitos have been found in the United States. Of the remedies in use in houses the burning of pyrethrum powder and the catching of mosquitos on the walls in kerosene cups are probably the best, next to a thorough screening of doors and windows and the use of mosquito bars about the beds. The remedies mentioned for bites are glycerin, a lump of indigo, and household ammonia.

Care of the Feeble-Minded.—Dr. A. W. Wilmarth, in a paper read before the recent meeting of the American Medical Association, made a difference in the classification of the lower grades of mental deficiency, idiocy and imbecility, and the higher types of feeble-minded and backward children. He said that at an early stage of mental development a child begins to notice objects, lights, persons, sounds, etc.: if these manifestations of intelligence be long delayed, it may be inferred that the child is deficient in sight or hearing. As delay in walking indicates backwardness in physical development or the presence of paralysis, so will delay in the development of speech be a sign of mental deficiency. If speech be wanting at four years, one may suspect permanent mental defect: if it does not develop at six years the suspicion becomes a certainty. At seven years the child emerges from the inquisitive stage when it asks all sorts of questions, answerable and unanswerable, about everything imaginable, and begins to analyze the facts gathered during that stage, putting them together into ideas. It is then that systematic teaching should begin. With feeble-minded children it is not a question of judgment or morals, but the question is whether a child learns as much as a normal child does at the same age. After fifteen the diagnosis is comparatively easy. The treatment of feeble-minded children of the higher types should consist, in addition to the necessary medication for whatever physical ills be present, of systematic training of the mind in properly conducted institutions. The author believes that the only way to stimulate the minds of these children is to arouse their imitative tendency, and this can take place only in the presence of the rivalry and companionship of an institution. In the family, no matter how wealthy, this system cannot be maintained, and the discipline is the more lax because the backward child is regarded with special indulgence.—*The Nursery.*

Ptomain Poisoning.—Regarding the symptoms of meat poisoning, Dr. Thompson, Professor Osler, and other well-known authorities appear to agree that the symptoms are substantially the same in each case. These symptoms may follow almost immediately or after an interval of several days. The former is much the better for the patient, because the sooner the alimentary canal is relieved from the poisonous material by vomiting and diarrhœa, the greater the chance of recovery. In the majority of cases there is a latent period of from twelve to thirty-six hours between the taking of the tainted food and the development of the symptoms. Ballard found that in observing fifty-one cases of meat poisoning, a period of twelve hours elapsed in five of the cases before the symptoms developed. In thirty-four cases between twelve and thirty-six hours elapsed, and in eight cases between thirty-six and forty-eight hours elapsed. There were only four of these fifty-one cases in which it took a longer period than forty-eight hours for the symptoms to develop. According to Dr. Thompson, the symptoms usually develop suddenly and with violence, but occasionally the development is preceded by an indefinite uneasiness on the part of the patient, nausea, lassitude, and abdominal cramps. When the symptoms develop suddenly, they are preceded by rigor with vertigo, or faintness, or a violent headache. Sometimes there is great difficulty in breathing, and there may be cold perspiration and sudden severe pains in the upper abdomen or in the thorax, and especially between the shoulders. Intense thirst has also been observed. Soon after one or more of these symptoms have appeared there is violent colicky pain in the bowels accompanied by nausea, retching, and vomiting. There is an extreme degree of muscular prostration, which comes on suddenly and prevents the patient from standing. This may be due to the abdominal pain, but it also occurs independently. The tongue is dry and coated with a thick, brownish-yellow fur in the middle, but the margins are of a bright red with distinct, minute, nipple-like projections. Fever is usually present, and the temperature may rise to 103.5° or 104° F., although the skin may feel cold and moist. The pulse is somewhat accelerated, and the rate may reach 130 or 140. Occasional symptoms which have been noted by Ballard, according to Dr. Thompson, are severe cramps in the legs and arms, convulsive twitchings of the muscles of the face and hands, stiffness in the joints, and various abnormal sensations such as numbness, tingling, and flashes of cold and heat in the extremities. There may also be drowsiness, intolerance of either natural or artificial light, and in the worst cases unsound nervous excitement or mild delirium. If the poison results fatally, the prostration increases, the pulse grows rapid and feeble, and rapid emaciation follows. The patient becomes extremely blue about the lips, and passes into a state of collapse resembling that of the last stages of cholera. In the more severe cases, if convalescence follows the attack it is prolonged, and the weakness of the patient may be fully as great as after some infectious fevers, such as cholera or yellow fever. Dr. Thompson says that the diagnosis is almost always obtainable from the history of the case in connection with the symptoms already described. When the cause of the poisoning is ptomains from canned food, the only difficulty consists in determining whether the poisoning is the result of eating the tainted meat or of acute metallic poisoning from chloride of zinc, tin, or lead used in the process of soldering the can.—*The Sun.*

Fat Food as a Preventive of Consumption.—Dr. Bell says that fat as an article of diet furnishes the potential force necessary for the conversion of other food material into organic tissue and to maintain the bodily functions. Prof. W. O. Atwater, in one of his most recent contributions on the nutritive value of foods, in comparing nutrients in respect to their fuel values, their capacities for yielding heat and mechanical power, states that "one pound of protein, lean meat or albumen of egg is just about equivalent to a pound of sugar or starch, and a little over two pounds of either would be required to equal one pound of the fat of

meat or butter." The mistake commonly made with reference to the use of fat food is that it is only or especially applicable in cold climates, an erroneous inference, the same as that cold is preventive of consumption. That fat is the almost exclusive food in Arctic regions is because other food is not obtainable, not because of the frigid climate. It is necessary food, though not in such excess at all times and everywhere, to supply the potential energy required by the organism to construct the tissues and maintain the body, the temperature of the body being about the same in all climates. Fat does not stand alone in this regard except under such extraordinary circumstances as those referred to. Carbohydrates of various kinds contribute to the same functions as fat under ordinary conditions, but they do not suffice to maintain the stamina of the organism to the highest degree anywhere without the assistance of or being supplemented by some kind of fat.—*The Sanitarian.*

Sweat Shops as a Means of Spreading Disease.—Dr. Roche recently delivered a lecture on the above subject at Dublin. He said it was not necessary for him to show that clothes as clothes carried infection. In the case of whooping-cough a person might carry infection in his clothes, and it might be retained in them for an indefinite period. It was therefore absolutely necessary that the making of clothes should be carried on under circumstances that should put them beyond all suspicion of infection. Consumption was an infectious communicable disease, and some time ago he had suggested that infection was carried in clothes. *The Lancet* had remarked that suggestion, and as a result experiments were made in America and elsewhere which proved that the germs of consumption would live in clothing for an indefinite period and would spread infection. It was no exaggeration to say that sweating opened the door for the spread of consumption in the families of those who bought, used, or wore clothes manufactured under the existing sweating-system.—*Sanitary Record.*

Infectious Diseases on Board Ship. — Staff Surgeon W. J. Colborne of the British navy read a paper on the above subject at the recent meeting of the British Medical Association. In brief, he said that the space alloted to sick on board ships of war was limited. Though limited it was sufficient for all ordinary purposes; yet provision should be made for infectious diseases, for observation, and for isolation. On visiting a port the medical officer should make inquiries as to the prevalence or absence of infectious diseases, the extent and the district infected, in order to warn the men against visiting that district. The ship should remain in that port only according to circumstances, and no longer. Persons visiting the ship, as washerwomen, etc., should be carefully supervised. All minor ailments in that port occurring on board ship should be carefully watched, and isolation practised when a case was doubtful; messmates as well as the sick man should be watched. A proper place for isolation must be found either below or above decks. The ventilation was important, as it should lead directly out above decks and not lend itself to the dissemination of infection between decks. All such ventilators should be stopped up. The patient and the attendant should not leave the apartment. When no apartment could be found a portion of the deck should be totally screened off from deck to deck, and the screen kept moist with perchloride of mercury solution, 1 : 1,000. No intercourse of any sort should be allowed with the outside, not even for food. If the patient were landed to hospital the attendants, the boat, and the crew should be disinfected by appropriate means. In smallpox every man should be revaccinated. If feasible every infectious case or even cases under observation should be landed. By the above means epidemics on board ship could be easily limited and stamped out.

Death Rate of Chicago.—The bureau report of the department of health of the city of Chicago gives the death rate for the year ending April 30, 1900, at 14.82; for 1899 at 14.38; for 1898 at 13.99; for 1897 at 13.98; for 1896 at 14.82. These figures are based upon a population of 1,750,000.

Decreasing Birth Rate in Europe.—New statistics demonstrate the fact that in all the countries of Europe, with the exception of Russia, the percentage of increase by births has been diminishing since 1891, the average decline being 3 per cent. The greatest difference is shown by England, where births have receded from 34 per cent. to 29.1 per cent., and the smallest by Norway, namely, 0.1 per cent. From 1871 to 1875 the increase by birth in Germany was 39.9 per cent., but in 1891–95 this had sunk to 36.3 per cent., and in the year 1897 it went down to 36 per cent. The general average from 1881 to 1885 was 36.8 per cent., but is now 36 per cent. More noteworthy is the decrease in Austria, where in the course of twenty-five years it has dropped from 39.5 per cent. to 37.4. In Belgium the percentage in 1871 was still 32.1, but in 1897 only 29; and in France the shrinkage in the same period was from 25.5 to 22.4. Next to Norway the most favorable data are reported from Switzerland.—*Medical News.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended September 29, 1900:

		Cases.	Deaths.

MEDULLARY NARCOSIS (CORNING'S METHOD): ITS HISTORY AND DEVELOPMENT.

BY L. MARCUS, M.D.,

NEW YORK.

THIS method of anæsthesia, which is engrossing the attention of the entire profession, appears to me to have taken a permanent place as a valuable therapeutic agent. It seems but proper at this time to view it from its historical side. While not wishing to bring about a controversy similar to that caused by the introduction of ether as an anæsthetic, credit should be given to the one who not alone was the first to use this method, but took the pains to let it be known to all in several monographs published in our representative journals.

J. Leonard Corning,[1] of New York, in 1885, is the first gentleman to record spinal anæsthesia; he reports his experiments tried on a dog and the human subject. In this his first report he claims that it is unnecessary to inject the medication into the spinal canal, stating "that in the human subject numerous small veins (venæ spinosæ) run down between the spinous processes of the vertebræ, and, entering the spinal canal, join the more considerable vessels of the plexus spinalis interna"; that by this arrangement of the circulation the cocainization of the cord would be obtained.

The record of his experiments is as follows: (I.) He injected twenty minims of a two-per-cent. solution of cocaine into the space situated between the spinous processes of two of the inferior dorsal vertebræ. Five minutes after the dog had been injected he noticed inco-ordination of the lower extremities. A short time after, on testing with the faradic current he noticed anæsthesia of the region supplied by the cord below his point of injection. Four hours later the animal had entirely recovered. In Experiment II. he injected in a human subject, between the spinous processes of the eleventh and twelfth dorsal vertebræ, thirty minims of a three-per-cent. solution of cocaine. After the lapse of six or eight minutes, having obtained no results, he injected a similar quantity into the same place. Ten minutes later the subject complained that his legs "felt sleepy." Sensibility was impaired when tested by the electrical current. The impairment "was principally limited to the lower extremities—the lumbar regions, the penis, and the scrotum." When standing the subject complained of dizziness; the ability of distinguishing differences in pressure seemed to be well preserved. He was able to pass a sound almost unnoticed, though this was usually accompanied by considerable pain. The pupils were slightly dilated. The constitutional symptoms noted were headache, slight vertigo, but no nausea. The subject experienced tingling sensations and numbness of his lower extremities until night, also dryness of the throat and mouth accompanied with mental exhilaration, probably due to the amount of cocaine injected, over gr. iss. The motor functions were not disturbed, as the patient was able to walk an hour after the injection, though sensibility was still impaired to a marked degree. He closes this report of his first experiments with the following remark: "Whether the method will ever find an application in genito-urinary or other branches of surgery, further experience alone can show."

The utility of this method so impressed Corning that he continued his experiments and widened its field of application in neurology, reporting his results in 1888.[1] In this article he describes his technique and gives illustrations of a trocar and needle for this special method. It appears, though he was not aware of it, that all of his injections which were followed by a favorable result must have been made into the spinal canal; as Marx[2] has shown that when the cocaine solution is injected around the cord, the phenomena of anæsthesia or the symptoms of post-operative insults are not obtained.

It is in his work on "Pain."[3] that he records the definite results, for which I believe he should receive the credit of being the first to try medullary narcosis for therapeutic purposes; and by his results of anæsthesia opened up the field for the possibilities of operating in or upon the analgesic areas.

In the chapter headed "Local Medication of the Spinal Cord," he carefully weighs the possibility of danger following lumbar puncture, stating: "As to the question of possible injury arising from pricking the filaments of the cauda with the needle, it must be borne in mind, in the first place, that serious disturbances of sensation and motility, having their origin in the cauda, are always due to gross lesions and not to insignificant circumscribed causes." The very fact that the cauda is composed of a great number of filaments, that these fill out the entire canal and are widely distributed, would *a priori* lead us inevitably to this conclusion did we not know inductively from clinical histories and subsequent post-mortem investigation that such is the case.[4] Secondly, we must remember that the wounding of a nerve stem (and the cauda is nothing more than an aggregation of nerve stems) with a fine, sharp needle is practically without significance. There is an interesting observation bearing on this point in Weir Mitchell's well-known book on nerve injuries, which we may here apply with perfect legitimacy. "The passage of a needle into the nerve of an animal causes," he says, "usually a little bleeding, which passes away without grave results.[5] Such a statement applies to simple puncture with a fine needle. Wounds made with an awl or other coarse instrument may, of course, set up the symptoms of circumscribed neuritis." This removes all possible immediate or remote injuries referable to a puncture made below the limits of the true spinal cord.

His *modus operandi* was as follows: "A small trocar, half an inch long and of the diameter of a wax match,

[4] Vide "Injuries of the Cauda Equina," by William Thorburn, M.D., Brain, vol. x.

[5] "Injuries of Nerves and their Consequences," by S. Weir Mitchell, Philadelphia, 1872.

was first thrust through the skin between the second and third lumbar vertebræ. A long, fine, hollow needle, screwed to an ordinary hypodermic syringe, was then passed through the opening in the trocar and down through the soft tissues adjoining the ligamentum interspinosum till the spinal canal was entered. The entire contents of the syringe were then emptied upon the fibres of the cauda equina." The solution injected consisted of tinct. aconiti, gtt. v.; cocainæ, gr. ss.; aquæ, ℥ i.

In from five to eight minutes the patient complained of tingling sensations in his lower extremities. On examination, there proved to be a decided impairment of tactile sensibility, "amounting in certain localities, particularly in the lower third of the thigh and ankle, to a positive anæsthesia." His error of technique was due to the fact that he inserted his needle with the syringe attached; the cerebro-spinal fluid was not allowed to escape, and only in the presence of this fluid is it possible to know absolutely and definitely whether or not the canal has been entered.

If the original literature referred to by me is thoroughly examined, I believe that there will not be a dissenting voice against giving J. Leonard Corning full credit for having introduced medullary narcosis.

Five years elapsed after the last article of Corning, when the attention of the world was again called to this form of anæsthesia by A. Bier, in 1899, in his original monograph.[1] He experimented with it, and was able to obtain anæsthesia sufficient to do any operation on the lower extremities.

The honor is due him for having established it as a new anæsthesia in surgery. He used Quincke's method of lumbar puncture, but kept his needle plugged until he believed he was in the spinal canal. He was very careful not to lose any more fluid after establishing the fact that his needle was in the canal; he then attached his syringe (he prefers a Pravaz) and injected his solution of cocaine, leaving the needle attached to the syringe *in situ* for two minutes so that the solution should not escape through the artificial canal made by his puncture. The skin puncture he sealed with collodion. He made his puncture painless by using Schleich's infiltration down to the vertebræ. He obtained signs of anæsthesia five to eight minutes after injecting, the patients complaining of tingling sensations and formication in the legs. His longest anæsthesia lasted forty-five minutes.

The quantity of cocaine he used varied from 0.005 gm. to 0.01 gm. The area of anæsthesia varied in his different cases; in some it extended to the mammæ, in others as high as the neck. He believes that the diminution of sensation is due to the effect of the cocaine upon the "scheidenlosen Nerven," and perhaps the ganglion cells. He reports the results of having himself injected as well as his assistant. The report of his personal case is interesting because it shows the result when too much spinal fluid is lost, and the proper treatment, rest is not obtained; likewise his assistant, though he lost very little spinal fluid, suffered by trying to pursue an active life following his injection. He believes it necessary after every injection to demand absolute rest to lead to a rapid recovery. The sensibility to appreciate touch remained intact in most cases, and was absent only when large amounts of cocaine were used.

The constitutional symptoms he noted were headache, vomiting, sweating, slight chills usually soon after the injection, rise in temperature (which was not of a surgical nature) usually occurring within a day. He noted nothing of a dangerous nature, but believes it is contraindicated in hysterical or excited patients.

A short time after Seldovitch[2] confirmed Bier's results, having also experimented on dogs. The disagreeable symptom of rise of temperature he attributed to the cocaine, which, he claims, has been proven to occur frequently when this drug is given hypodermically. He failed to get any rise of temperature when a saline solution was injected into the spinal canal of a dog. He emphasizes the necessity of asepsis in using this method.

The next step in its advancement was made by Tuffier,[1] who extended the field of operation from the lower extremities, established by Bier, to the genito-urinary organs, rectum, and intestines. He is the first to report a large number of cases; they were comprised of both sexes. He recommends a platinum needle, 9 cm. long, with an external diameter of 1.1 mm. and internal one of 0.8 mm., the oblique bevel much shorter than that of the ordinary aspirating needle. He also uses the Pravaz syringe. He locates his point of puncture by drawing an imaginary line joining the crests of both ilia, this crosses the centre of the fourth lumbar vertebra, and from this point it is easy to find the space between the fourth and fifth, where he prefers to inject. He prefers the scorching position, as all others he has tried are subject to flexure or deviation of the vertebræ, which makes the puncture more difficult; another obstacle is deformities of the spine. He never injects the solution of cocaine until he sees the escape of cerebro-spinal fluid. He lays great stress on the necessity of using a fresh sterilized solution, as he has found it becomes rapidly inert from frequent sterilization. The maximum quantity of cocaine he used was 15 mgm. He noted the same constitutional symptoms as Bier; for the vomiting, which, he says, comes on soon after injecting, he recommends the use of ice given internally. He has found the headache the most constant symptom. It varies greatly in duration and severity; most frequently it is light and lasts a short time, but he has seen it severe and continue for two days. His anæsthesia lasted from one to one and a half hours.

The first report of its use in obstetrics was made by O. Kreis.[2] He noted no disturbance of the muscular power of the uterus; the contractions occurred just as frequently, also with apparently the same intensity as before the injection. The patient, though not suffering any pain, complained that her abdomen felt as if it were being stretched. The pressure of the head, the stretching of the vulva, the entrance of the forceps, and the extraction of the head were appreciated by the patient, but absolutely devoid of pain. The abdominal muscles remained at rest, lacking the stimulation of the pain due to pressure of the head; but when the patients were told to bear down they were able to exert as much power as before receiving the injection. No disturbance of the motor function of the uterus was noticed at any time. His anæsthesia averaged about two hours in duration. He does not believe it is advisable to use it when the assistance of the abdominal muscles is required, or in frightened or excited patients who would scream or cry out, although suffering no pain. He believes it is useful in cases complicated by heart or lung disease, or when the operator cannot obtain proper assistance.

The first extensive report and application of this method in this country was made by Marx.[3] He experimented also with eucaine, but was not able to get any anæsthesia. He injected a saline solution into the spinal canal and obtained the same constitutional effect as he obtained by injecting cocaine, minus anæsthesia. He used nitroglycerin, gr. $\frac{1}{100}$, to counteract symptoms which, he believes, are due to the shock of

the central nervous system, and met with varied results. He has tried hydrobromate of hyoscine, gr. $\frac{1}{200}$ given hypodermically, immediately after finishing his spinal injection, or at the first sign of any of the disagreeable symptoms. He has used from gr. $\frac{1}{6}$ to gr. $\frac{1}{3}$ of cocaine for one injection, and has given as much as gr. $\frac{3}{4}$ within an hour. He objects to injecting any other drug than cocaine into the spinal canal, as he has seen toxic results from the combination of morphine sulphate, gr. $\frac{1}{6}$, in his solution. His anæsthesia has lasted from one to five hours, and by repeated injections he has kept a patient under its influence for eight hours. He recommends that the patients be blindfolded and have their ears plugged with cotton; that it is necessary for the operator and his assistants to refrain from any unnecessary noise or talking. The patient should be reassured constantly.

He has not met with any dangerous results to mother or child, and believes it has opened up the field for normal labor without any pain. He terminates his report by stating that he thinks it is indicated in a prolonged painful first stage, convulsions present or threatening, in septic cases for explorations and operations.

In a personal interview with Dr. Marx, I am informed that he has given cocaine puncture for abdominal and vaginal hysterectomy, the operator being Goffe, of New York, the results in both cases being ideal.

Other successful cases have been reported, but they give us nothing new in technique or application.

The question now is to ascertain a technique by which the area of anæsthesia will be constant in all cases.

I take pleasure in thanking Dr. Ware for the references he has given me.

In closing, it is needless to say that this being a surgical procedure, asepsis is an absolute requisite to avoid fatal sequelæ.

1215 Madison Avenue.

THE MODERN TREATMENT OF PULMONARY TUBERCULOSIS.

By M. J. BROOKS, M.D.,

STAMFORD, CONN.,

PHYSICIAN-IN-CHARGE STAMFORD PULMONARY SANATORIUM; MEMBER CONNECTICUT STATE MEDICAL SOCIETY, ETC.

Upon the threshold of the twentieth century there dawns a new era in practical therapeutics—no less a boon than the successful treatment of the greatest scourge to which human flesh is heir.

A short while, a bit more patience, and a trifle more effort are still requisite for its consummation and general acceptation. A short time is still required before this knowledge will be appreciated by the great body of general practitioners.

The present is formative. It is a transitional period. The profession in general has scarcely as yet emerged from the gloom of empiricism in the treatment of this disease, through which it has been groping from time immemorial.

No single period in the world's history has been so fraught with practical progress in phthisio-therapeutics as the closing years of the present century. Perhaps no similar period has possessed so many ardent workers in this field, nor has greater amount of effort been expended.

The studies and perquisitions of Cornet, Strauss, Chauveau, Cohnheim, Villemin, Klebs, Aufrecht, Koch, and others have served to elucidate and exemplify its etiology and pathology. We are indebted to these gentlemen for a clear and accurate conception of the causes and factors involved, without which there could be no rational treatment.

A brief reiteration of certain etiological and pathological principles is essential to a proper comprehension and lucid understanding of the modern methods of successful treatment.

Tuberculosis is a disease of crowding,[1] of unsanitary dwelling,[2] of deficient ventilation, of insufficient use of soap[4] and water,[5] of deficient and insufficient feeding,[6] of uncleanliness,[7] of defective hygienic environment;[8] in short, of departure from the conditions of a healthy animal life.[9]

True it has a specific infectious organism, but the bacillus is only the "histological exponent, not the whole of the tubercle, much less of the disease."[10]

Local tuberculosis, regardless of its situation in the human economy, has the same characteristics—the *locus minoris resistentiæ* and the proliferation of connective-tissue cells resulting in a sequestration of its offending concomitant infective agent.

Remove the primordial etiological factors enumerated and the disease abates; if neglected, further infection ensues. That is the so-called mixed infection. The ubiquitous pyogenic organisms find a suitable soil, and then is presented the typical clinical configuration of consumption.

Pure local tuberculosis, whether pulmonary or articular, does not possess the time-honored and respected signs of inflammation—*rubor*, *dolor*, *tumor*, *calor*, *et functio læsa*. Pulmonary tuberculosis is quite afebrile and without exudation, but add mixed infection and pulmonary phthisis is the sequence. In other words, phthisis is pulmonary tuberculosis plus a pyæmia or septicæmia. The due appreciation of this complication is of paramount importance, for almost all the dreaded symptoms of phthisis are the result of this pyogenic superinfection.

The subject of mixed infection has recently been studied with great care by one of the cleverest of bacteriologists, Sata, of Tokio, Japan. He has shown that the broncho-pneumonia of consumptives is due invariably to these mixed bacteria. The predominant micro-organisms are the streptococcus pyogenes, staphylococcus pyogenes, diplococcus of Fraenkel, and Pfeiffer's influenza bacillus.

Sata,[11] Pfeiffer,[12] and Brieger,[13] in harmony with Petruschky, attribute the hectic fever and night sweats to the work of the streptococcus. These gentlemen have been able to recognize the so-called streptococcus curve in the fever charts of many consumptives. Further, the staphylococcus pyogenes, from its known liquefying action upon connective tissue, is in the main responsible for the breaking down of pulmonary tissue. Pfeiffer's bacillus as well as Fraenkel's often causes consolidation, thus hastening the progress of the disease. The bacillus pyocyaneus of Gessard gives the characteristic greenish coloring to the sputa. The micrococcus tetragenus described by Koch and Gaffky is frequently found in phthisical sputa as well as many other micro-organisms having more or less pathogenic qualities.

Now as for treatment. It is obvious, again to quote Brieger,[14] that a specific serum cannot meet the indications furnished by a mixed infection. It has been repeatedly noted that in the contest between the system and the organisms associated with phthisis, the leucocytes and their alexins play a lesser part than in any other infectious disease.[15]

Yet there are many who still have faith, for instance, in Koch's tuberculin in spite of Virchow's protestations, or Hausemann's and Baumgarten's assurance that an eruption of tubercles occurred regularly during the injections; or Bozzolo's[16] observation that it converted a chronic process into an acute; or Papillon's[17] evidence that the reaction was to be obtained in any ordinary cachexia; or Landouzy's,[18] in general erethism.

There are yet advocates of Maragliano's serum notwithstanding De Renzi's[19] and Fraenkel's[20] demonstrations as to its futility; of Klebs' and Hutinel's, in spite of Debove's,[21] Blache's,[22] and my own[23] investigations. Portucalis'[24] recent advocacy of a serum prepared from tertiary syphilitics, which he considers "would be of great advantage to consumptives," should surely require no contradiction. It is manifestly absurd.

But it is hardly necessary to mention each and every one. Omeltchonko[25] has experimented with a variety of sera and found them wanting. The consensus of opinion it seems is with Beck,[26] Rabinowitsch,[27] Osler,[28] Richardiere,[29] Sir Herbert Maxwell,[30] Pye-Smith,[31] and others, that all sera, diagnostic or specific, have proven nugatory in their application to this disease.

As for drugs: Centuries of experimentation with every ingredient mentioned in the pharmacopœia have given us not a single one that has the slightest favorable action upon tuberculous processes.[32] Even the much vaunted creosotes, guaiacols, and the like have proven in some instances inert,[33] in others injurious.[34] However, be they inert or injurious they have certainly, to use the words of Osler, "no essential influence on the progress of this disease."[35]

Again, the virtues of climate, altitude, and atmospheric pressure, upon which so much reliance has been placed, have dwindled beneath the searchlight of close investigation. The old theory of immune zones is no longer tenable. The bacillus is found regardless of temperature, of elevation, of moisture, or prevailing winds.[36] The disease prevails regardless of demographic conditions or geographical positions.[37]

Thus we find Crowley[38] and Duckman,[39] of California, inveighing against the practice of sending the tuberculous to their State; the Honolulu health reports[40] showing progressive increase in tuberculosis among the natives; Girdner[41] affirming the percentage among the citizens of Asheville, N. C., to be the same as that of Manhattan; Newton[42] assuring us of its prevalence among the natives in the Adirondacks; Davies[43] demonstrating tuberculosis rampant even upon the Isle of Man, "where the temperature is equable, abundant sunshine, and fogs unknown." Yet the climate of these places has frequently been lauded as a specific in consumption.

Detweiler[44] and Blumenfeld, it is affirmed, were the first to prove these factors unessential to treatment. Lannelongue, Archard, and Guillard[45] have recently carefully studied the question of the influence of climate upon the evolution of tuberculosis. Their conclusions are as follows: "In certain regions the disease is rare, and its relative infrequency is attributable solely to the mode of life of the inhabitants. The improvement which has been noted in patients at health resorts which have a reputation for the cure of phthisis is due alone to the effects of the different methods of treatment adopted, and cannot be attributed to the region or place." F. Hueppe's[46] deductions were practically the same.

That climate is unessential to successful treatment was the verdict of the International Medical Congress, held at Moscow in 1897.

Dr. Pannwitz's report as general secretary of the Berlin Congress of Tuberculosis contains the following: "The fact has been proven that tuberculosis can be treated successfully anywhere without regard to climate."

"Elevation," to quote Braine-Hartwell Birmingham,[47] "of a few hundred feet may be desirable, though not necessary." J. E. Birmingham[48] declares from much experience that "elevation has no influence whatever over this disease. Patients do as well at sea level as at high altitudes."

Atmospheric conditions are unimportant. Barometric pressure does not hold the slightest causative relationship to any disease.[49] Professor Stewart in his address before the International Congress showed that the results obtained in Edinburgh with its "rain and mist and east winds" were equal to the most favorable obtained in Germany.

If further evidence along this line be desired, I refer to Walker,[50] Burton-Fanning,[51] von Schrotter,[52] Otis, Knight,[53] Shaper,[54] Girdner,[55] Tew,[56] Roane Brunnon,[57] Hillier,[58] Wolff, and others.

If drugs, sera, climate, altitude, and atmospheric pressure have proven inefficient, in what does the cure consist?

The sum substance of successful treatment resolves itself into the rational application, conversely, of its fundamental causative factors; the diametric antithesis of its so-called predisposing etiology; plus, to use the words of Moeller,[59] "the summation of many minor curative measures, each of which, perhaps, if taken by itself has but slight effect, but collectively productive of the greatest good."

It is apparent that these measures, with their multitudinous details incident thereto, can properly be carried out only in institutions where the patients are under constant, competent, sincere, painstaking medical supervision.[60]

To quote a recent author, "the value of sanatoria treatment has been too incontrovertibly demonstrated to permit of any difference of opinion."[61] To mention the advocates of sanatoria treatment for this disease would be but to name every student of the subject the world over, *nemine contradicente*.

Now as to the armamentaria of sanatoria. Perfect sanitation and prophylaxis, scrupulous cleanliness, the routine of occupation, the systematic hygienic regimen, aerotherapy, Dauerluftkur, the time air cure of the Germans, efficient nursing and the like, it goes without saying, are of prime importance. There are other measures, however, not generally appreciated, although none the less valuable, which are deserving of consideration. Foremost among them is inhalation, which dates from the period of Paracelsus. "There can be no questioning the fact," to use the words of Schroeder,[62] "that inhalation therapeutics play a great rôle in the treatment of phthisis." Dr. Penrose[63] of Johns Hopkins assures us that the antiseptic action of inhalation is manifested by the rapid disappearance of pus organisms from the sputum, and Burghart[64] and Brieger[65] are practically of the same opinion.

Antiseptics and the aliphatic hydrocarbons of the turpentine group are the ingredients generally used. They are administered by siphon or comminuter arrangement with compressed air. Of course, no sanatorium is complete without its inhalation chamber, as von Schrotter, Meissen, J. Lazarus, and others affirm, but from special study I am quite satisfied that an equally valuable method of application consists in charging the atmosphere of the entire institution with antiseptics by means of vacuum pumps and engine.

An antiseptic or medicated atmosphere constantly maintained, particularly during the night's rest, is certainly, to say the least, an efficient coadjutor of the inhalation chamber. It destroys much of the mixed infection, limits toxin necrosis, loosens and facilitates the removal of alveolar and tubular exudations, and allays local tissue irritation. P. Lacroix[66] claims still further from his experiments with medicated air that the tubercle bacilli as well as the microbes of mixed infection are destroyed. Properly administered, then, inhalation is without doubt the most potent single remedy at our command in the treatment of this disease.

Hydrotherapy is manifestly an essential to successful treatment. It should, however, be systematically

and rationally carried out as part and parcel of daily routine. So important is this measure that many enthusiasts, such as Kuthy[67] and Winternitz,[68] maintain that cures may be effected by this means alone.

The carbonated or Nauheim bath has been found valuable in its application to this disease; of course, minus the resistant gymnastics. It is a certain means of steadying an intermittent or irregular pulse, or of reducing its frequency. By promoting a superficial capillary congestion it likewise tends to relieve visceral engorgement. It is, without doubt, a superior substitute for the pneumatic cabinet.

The importance of diet in a synthetic condition is self-evident. Wilcox[69] and more recently Harris[70] have carefully studied the subject, but it is a wide field and worthy of further investigation. Suffice it to say that feeding should be slightly in excess, but the food should be well selected, nutritious, temptingly served, and, of course, properly cooked.

Symptomatic treatment is strictly a subsidiary measure. Schroeder[71] observes that despite the innumerable substances which have been uselessly employed in connection with the therapy of phthisis, there are certain indications which we are justified in meeting with symptomatic remedies, as drugs and nutrient preparations; as, for instance, hyperpyrexia, hæmoptysis, insomnia, profuse night sweats, the pains accompanying pleural, larnygeal, or intestinal infection, severe rigors, paroxysms of coughing, diarrhœa, collapse, and the like. At the same time it should not be forgotten that the tuberculous are as prone to the minor ailments as the non-tuberculous, and their innumerable complications or personal idiosyncrasies must necessarily be intelligently dealt with.

Exercise, which many of the earlier phthisiologists, notably Detweiler, deemed appropriate to treatment and encouraged, has of late been very much restricted. Dr. Edson,[72] a short time since, struck the keynote when he said that "there were indications in the pathology of this disease for rest. While physicians followed them as they applied to articular and laryngeal tuberculosis, they ignored them when the lungs were in question." Prof. William H. Thomson at a recent New York medical meeting averred that even at rest "the constant movement in respiration was a great hindrance to cure."

The advocation of golf and horseback riding in the treatment of phthisis *a priori* contravenes both pathological and clinical indications. In the light of present knowledge and experience Liegekur, therefore, supersedes Uebungskur. As Hillier[73] states, frequent and complete rest is imperative.

Lastly, it is hardly necessary to add that the secret of institutional success lies in the competency and sincerity of the physician in charge; "in his ability," as Muthu[74] puts it, "to discriminate and shape his treatment according to the physical requirements of the individual case."

In conclusion, permit me to add that the success of treatment is intimately connected with its early recognition; that pulmonary tuberculosis is positively curable. That it may be diagnosticated even without bacteriological examination, Fraenkel,[75] Fluegge,[76] Petrushky,[77] Anders,[78] Senator,[79] Bozzolo,[80] Giovanni,[81] and many others aver.

As to phthisis, however, it is of course dependent upon the extent of lung involvement and duration. The corollary is patent, that treatment must be effected early.

Sanatorium treatment for pulmonary tuberculosis is the achievement of the closing years of the century, and embraces in sum and substance modern and successful methods.

A CONSIDERATION OF THE ANATOMICAL CONSTRUCTION PREDISPOSING TO INGUINAL AND FEMORAL HERNIÆ, AND THE MEASURES TO BE TAKEN IN SECURING THEIR RADICAL CURE.[1]

By IRVING S. HAYNES, Ph.B., M.D.

PROFESSOR OF PRACTICAL ANATOMY, CORNELL UNIVERSITY MEDICAL COLLEGE, VISITING SURGEON TO THE HARLEM HOSPITAL, ETC.

In inviting your attention to the subject of inguinal and femoral herniæ nothing new or novel is promised. The importance of the subject alone justifies its frequent consideration. The careful study of any matter with which we are already reasonably conversant often proves valuable in bringing to our attention lesser facts we had nearly forgotten, and clearly defining others that had grown indistinct.

Fig. 1.—Cast of the Lower Abdominal and Pelvic Cavity of an Old Man (Sixty-five to Seventy Years). *a*, The external inguinal fossa (what are fossæ in the subject appear as tuberosities in the casts); *b*, the femoral fossa (the middle and internal inguinal fossæ have their negatives in the cast, but are not lettered); *c*, groove (blackened) produced by the deep epigastric artery.

My purpose to-night is stated in the title of the paper. I wish to ask you to review with me the peculiar construction of the body that, we may justly say, predisposes to the formation of an inguinal or femoral hernia. I acknowledge that I have had my doubts about the popularity of any subject so closely allied to anatomy, for many shy at the mention of this branch. Anatomy probably represents more than any other study the nightmare of our medical course. A report of cases operated on and cures obtained is more inviting, but is it as profitable to all of us as a study of the conditions which make a hernia possible and the steps to be taken to eliminate these conditions?

A hernia is the tumor and its coverings formed by the protrusion of a viscus through an opening in the walls of the cavity in which it is contained.

This paper is limited to the consideration of the indirect inguinal hernia, when the viscus passes through the inguinal canal, and a femoral hernia, when the escape takes place through the femoral canal. The permanent cure of these herniæ depends upon several factors. The principle which underlies the rational interpretation and management of these factors is that the abnormal conditions existing which allow the development of a hernia shall be restored to the normal.

In the normal individual there is no hernia, although certain facts of construction exist which predispose, at times, to the development of such an occurrence.

The more closely nature is imitated by the surgeon in the re-formation of the parts during an operation for hernia the more permanent will the result remain. It is therefore very essential, before we proceed to advocate any operation for the cure of this condition, that we know the arrangement of the parts when hernia does not exist, and the changes produced in the parts when it develops.

The Inguinal Region and Hernia.—The features of construction which predispose to an inguinal hernia are these:

First, the position of this region at the bottom of the abdominal cavity where effects of pressure are more pronounced. This operates also in the case of the femoral variety.

Second, the existence in these regions of areas of unequal curvature of the peritoneum.

The interior of the perineal sac reflects, of course, the shape of the abdominal wall and is not uniformly sphere-like, but presents certain ridges and hollows. In the inguinal region three ridges are found formed by the urachus passing from the top, and the obliterated hypogastric artery from the side of the bladder to converge at the umbilicus and still more externally the deep or internal epigastric artery, which extends from the external iliac in a direction upward and inward. Between the ridges formed by these three cords are depressions called the inguinal fossæ—internal, middle, and external. As we are limited in this paper to the oblique inguinal hernia we have to do with the last. This is usually quite pronounced. It is limited internally by the ridge formed by the deep epigastric artery, below by the line of Poupart's ligament, and above and outward smooths out into the general peritoneal wall. The significance of this pouch is this. Its deepest point is immediately over the internal inguinal orifice. It predisposes to the development of a rupture by concentrating at the orifice the force of intra-abdominal pressure. Such pressure may be no greater here than at any other point on the same level, but all other points do not have a potential opening leading through the abdominal wall, hence the effects of pressure are localized by the presence of this pouch.

Fig. 2.—Similar Cast from an Old Woman. The references are the same as in Fig

[1] Read June 11, 1900, before the Harlem Medical Association, and demonstrated by plaster casts and numerous dissections.

Should there be a state of weakness at the ring, as described later, a hernia may result.

Third. From the bottom of the fossa the funicular process of peritoneum extends onward through the inguinal canal to the scrotum. Usually this tubular structure is obliterated and only a thin fibrous cord remains, which may be hard to demonstrate. This is the normal condition and does not in itself influence the occurrence of a hernia. Should the tube remain open, either partially or completely, a hernia is not only possible but is extremely probable.

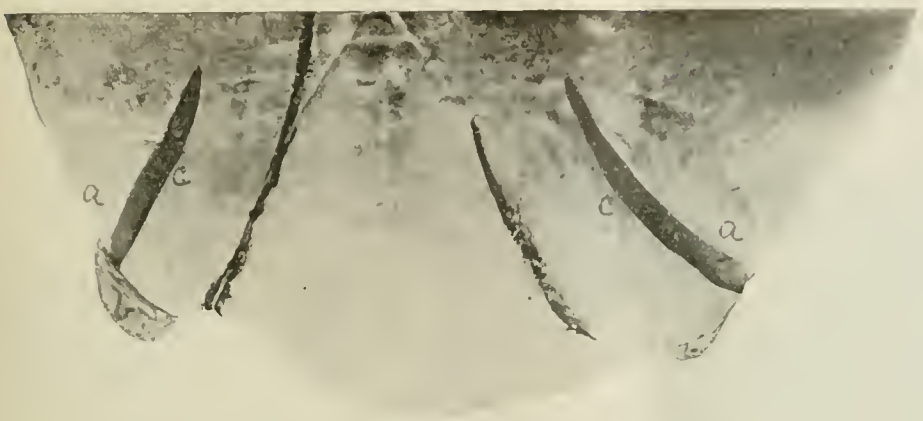

Fig. 3.—Similar Cast from a Young Woman. The references are the same as in Fig. 1.

Fourth. The next predisposing factor is found in the manner in which the elements of the cord itself converge at the internal ring. The vas deferens comes from the pelvic cavity at the inside of the internal ring, the spermatic vessels descend from the lumbar region above the ring. They meet and unite at the internal ring. Their junction forms a V-shaped figure, the apex of which is at the ring. This arrangement serves, no doubt, in a slight degree to direct a loop of intestine toward the internal orifice.

Fifth. There is a more potent factor in the fact that the cord traverses the abdominal wall. So long as nature determines that the testicle shall be worn externally, so long will the cord need to traverse the abdominal wall and a state of weakness will remain. I am hardly ready to advocate the placing of a testicle within the abdominal cavity merely to eliminate this feature of architectural weakness.

The larger and more vascular the cord the weaker becomes the abdominal wall about it, because the cord may be compressed by unusual pressure, its attachments to the surrounding parts weakened, and a knuckle of intestine may be forced between it and the margins of the inguinal ring. Repeated stretchings of this sort will tend to enlarge the orifice and allow the escape of intestine or omentum.

Sixth. The inguinal canal and rings. In order that we may all think of the same thing when these terms are used it is best to define them. By the internal inguinal ring is meant the opening, or really the potential opening, in the transversalis fascia, not the muscle, through which passes the spermatic cord in the male or the round ligament in the female. The external inguinal ring is the similar opening in the aponeurosis of the external oblique muscle through which the same structures pass, and the inguinal canal is the tract joining these rings and situated between the internal and external oblique muscles, which is occupied by the cord or round ligament *en route* from the abdomen to the scrotum or labium.

We all understand that these terms of rings, orifices, and canals are used because there are no better. There are no open holes or rings unless a hernia has existed or the dissector been at work. Normally the cord is snugly enclosed by the tissues at all points.

A word about just how these so-called openings are formed may not come amiss and will help to make clear the later statements.

In early fœtal life the testicle lies within the abdominal cavity below the future kidney. Gradually it works down until it comes against the internal surface of the abdominal wall. Preceded by a small pouch of peritoneum the testicle now passes through the transversalis fascia, the transversalis and internal oblique muscles, then between the latter and the external oblique muscle, traverses the last, and finally settles in the scrotum.

Now the testicle does not make any hole or rent in these layers of the abdominal wall, but stretches each layer before it. Each layer then contributes a long, funnel-shaped pouch covering the cord and testicle. Thus the transversalis fascia furnishes the layer called the infundibuliform fascia, which can be demonstrated for a short distance surrounding the cord and forming a funnel-shaped pit.

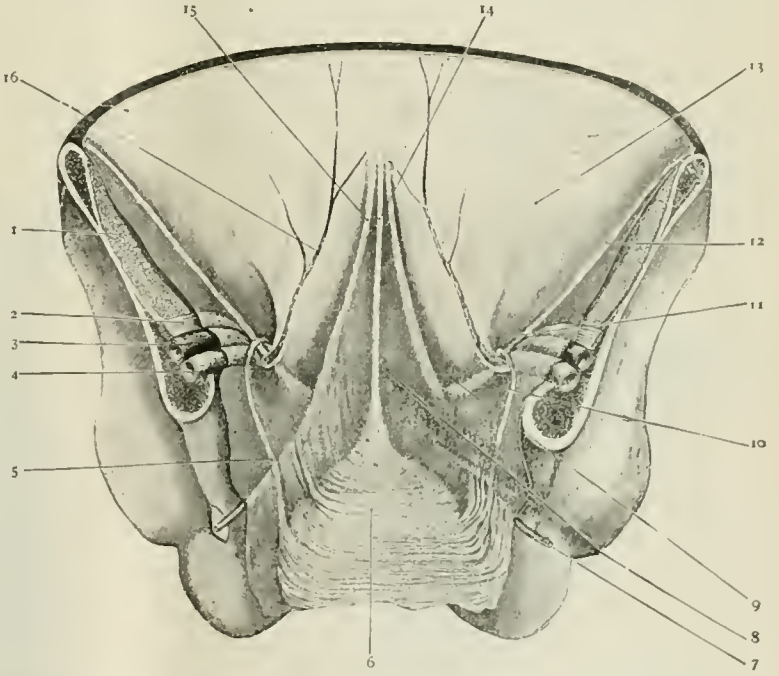

Fig. 4.—Posterior Surface of the Anterior Abdominal Wall. Peritoneum in position. Inguinal and Femoral Regions. 1, The iliacus muscle; 2, anterior crural nerve; 3, external iliac artery; 4, external iliac vein; 5, vas deferens; 6, bladder covered by peritoneum; 7, superior vesical artery (the still pervious portion of the hypogastric artery; 8, internal inguinal fossa; 9, the middle inguinal fossa; 10, femoral fossa; 11, external inguinal fossa; 12, Poupart's ligament; 13, peritoneum; 14, fold of peritoneum made by the urachus; 15, fold of peritoneum made by the obliterated hypogastric artery; 16, fold of peritoneum made by the deep epigastric artery.

The transversalis and internal oblique contribute muscular fibres as well as fibrous tissue to help in forming the cremasteric fascia. This layer is readily demonstrated, and becomes greatly hypertrophied in chronic scrotal hernia.

The external oblique furnishes a thin tissue called the external spermatic fascia, which also covers the cord and testicle.

We thus see that while the testicle may be said to pass through the abdominal wall, yet it does so only after protruding the thinned layers of this wall before it; these layers in turn furnishing the coverings for the testicle and cord and the variety of hernia we are discussing.

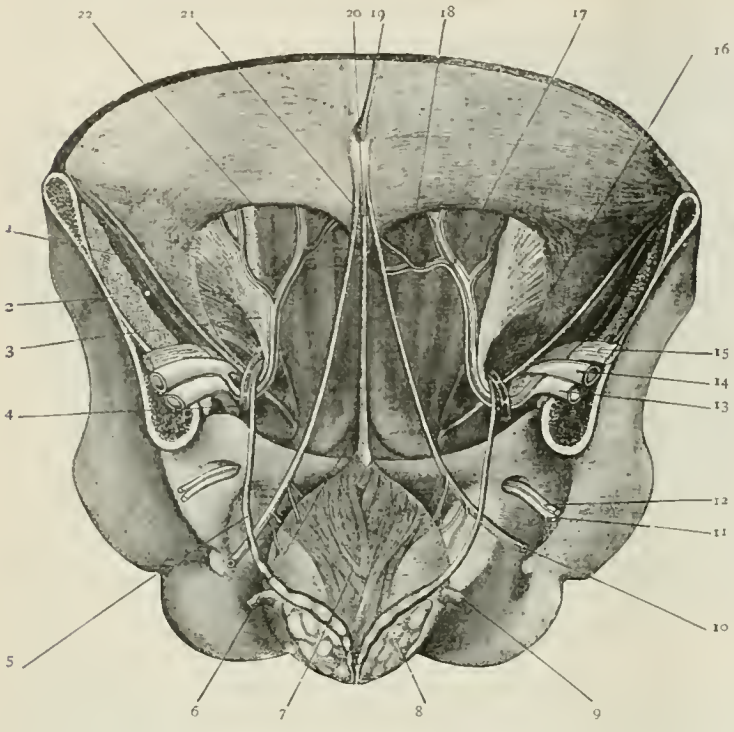

Fig. 5.—Posterior Surface of the Anterior Abdominal Wall. The Peritoneum removed. Inguinal and Femoral Regions. 1, Poupart's ligament; 2, the iliacus muscle; 3, semilunar fold of the transversalis fascia; 4, spermatic vessels; 5, vas deferens; 6, base of the linea alba; 7, the urinary bladder; 8, seminal vesicle; 9, the ureter; 10, superior vesical artery (the still pervious portions of the hypogastric artery); 11, obturator nerve; 12, obturator artery; 13, external iliac vein; 14, external iliac artery; 15, anterior crural nerve; 16, internal inguinal ring; 17, deep epigastric artery and veins; 18, rectus muscle; 19, suspensory ligament of the liver; 20, the urachus; 21, obliterated hypogastric artery; 22, semilunar fold of Douglas.

The union then about the rings, canal, and cord is always a weak one and easily destroyed. This makes the rings weak points in the abdominal wall. Yet this weakness in itself is not sufficient to cause the development of hernia unless some of the other factors are present.

The inguinal canal is about one and three-fourths inches long; that is, the two rings are this distance apart, measured along Poupart's ligament.

A weakness about the canal and rings will be found to consist in an enlargement of the rings and a shortening of the canal. These constitute most effective predisposing causes for a hernia.

Two rings there must be normally, and yet no hernia need result so long as these openings are normal in size, far apart, and each guarded by a strong fascia, the internal opening by the external oblique fascia, the external ring by the conjoined tendon.

The internal ring is still further reinforced by an active structure, viz., the common fibres of the transversalis and internal oblique muscles, which, arising from Poupart's ligament, arch over the cord and pass on as the conjoined tendon to be attached to the linea ilio-pectinealis.

Intra-abdominal pressure, then, in the normal subject serves to press the component parts of the abdominal wall together; the weak places are sufficiently protected by the stronger reinforcements, and no escape of viscera occurs.

The external inguinal ring is found presenting the appearance of a slit, caused by the divergence of fibres of the external oblique aponeurosis near the spine of the pubis, for the passage of the cord. The sides of the openings are called the pillars or columns of the ring. The further separation of the fibres of the external oblique is prevented and the weak place strengthened by some transverse fibres called the intercolumnar fascia. From this fascia and the pillars of the ring the external spermatic fascia passes on to the cord.

If the fibres of the external oblique, or pillars of the ring, are separated for an unusual distance, then both rings are weakened, the external directly, the internal indirectly, by impairment of its external support, and the condition becomes favorable for the development of a hernia.

In infancy and early childhood before the pelvis has developed the inguinal canal is a short affair, the rings are close together, and a state exists favorable for the development of hernia. If added to this there is an open funicular process, a rupture will probably appear.

Seventh. An abnormally long mesentery or omentum. The mesentery and omentum are probably unnecessarily long in case a hernia actually exists; still, it does not follow that an increase in the length of these parts is an active predisposing factor to hernia. In the cure of a hernia no account is taken of an elongated mesentery or omentum (unless the latter is hypertrophied), as the permanency of the result of the operation depends solely upon the repair of the abdominal wall and treatment of the cord.

The changes which are produced by a hernia depend to some extent upon the time of life when it appears and its duration. In early life an open funicular process will be occupied, and this pouch will form the sac of the hernia. In later life the hernial sac is acquired, either

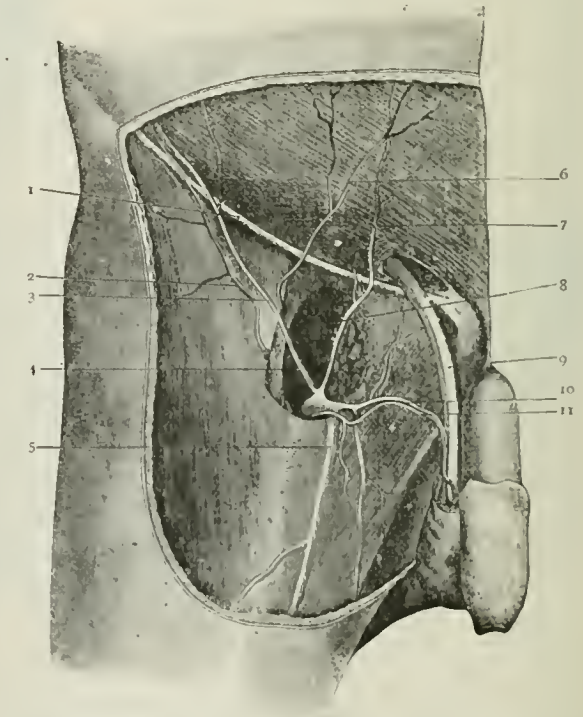

Fig. 6.—The Inguinal and Femoral Sections. Superficial dissection. 1, Poupart's ligament; 2, superficial circumflex iliac artery; 3, superficial circumflex iliac vein; 4, femoral artery (its position shown beneath the fascia lata by heavier shading); 5, internal saphenous vein; 6, superficial epigastric artery; 7, superficial epigastric vein; 8, cribriform fascia; 9, spermatic cord; 10, superficial external pudic vein; 11, superficial external pudic artery.

gradually or suddenly, by the invagination of the peritoneum in the inguinal fossa. In both cases the hernia has passed through the rings and canal into the scrotum, or labium, and there continues its development. I purposely omit reference to the numerous

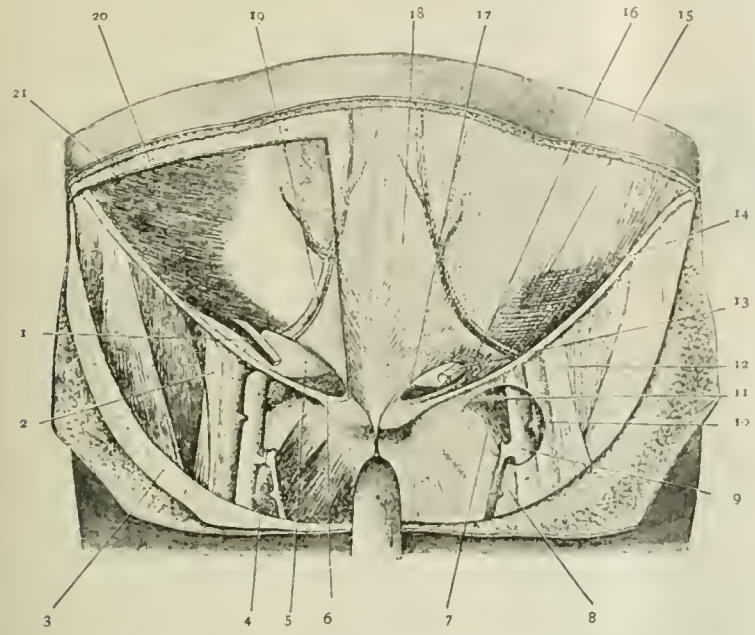

FIG. 7.—The Inguinal and Femoral Regions. Deep Dissections. 1, Cremaster muscle; 2, ilio-pectineal fascia—deep layer of the fascia lata; 3, superficial layer of the fascia lata; 4, Rosenmuller's lymphatic gland; 5, transversalis fascia; 6, Colles' ligament; 7, fossa ovalis; 8, internal saphenous vein; 9, femoral vein; 10, femoral artery; 11, falciform process of the fascia lata; 12, anterior crural nerve; 13, spermatic cord; 14, Poupart's ligament; 15, fibres of the intercolumnar fascia; 16, inferior crus of the external inguinal ring; 17, superior crus of the external inguinal ring; 18, aponeurosis of the external oblique muscle; 19, deep epigastric vessels—represented as showing through the muscles; 20, aponeurosis of the external oblique muscle; 21, internal oblique muscle.

varieties of the indirect inguinal hernia and content myself with the complete scrotal (or labial) form.

A rupture of this sort profoundly alters the normal construction of the region. The inguinal rings will be abnormally enlarged and the internal displaced toward the middle line, until it is found in a majority of cases directly behind the external, and the inguinal canal has been obliterated. The peritoneal sac presents various features into which it is not my purpose to enter, except to say that it is thickened and will usually communicate with the abdominal cavity by a narrow orifice that flares out funnel-shaped into the general peritoneal layer.

The various structures given as furnishing the coverings to the testicle and cord in turn become the coverings for the hernia. As they play no part, with the exception of the cremasteric fascia, in the development and cure of hernia, they will be ignored.

The cord itself undergoes changes. It becomes more vascular and hence larger. This increase in size is due chiefly to a varicose condition of the veins, produced by obstructed circulation, such obstruction being usually found at the internal ring. The omentum present in the hernia becomes in time thickened, and numerous adhesions may be formed between it and the sac or intestine. In the intestinal form the mesentery becomes elongated to allow the gut to descend.

The Radical Cure.—Given an oblique inguinal hernia, we now seek to find what measures must be taken to cure it.

My text at the beginning serves us now. It is this: Imitate and reproduce nature's plan of construction.

Let us see how this can be done at the ordinary operation. It is taken for granted that the sac has been opened, its contents have been dealt with, and the operator is now ready to proceed to close up the wound. To summarize the difficulties, it will be necessary to deal with the sac, the cord, and inguinal canal and rings.

The Sac.—The external inguinal fossa (in the peritoneum) cannot be entirely obliterated, but it can be made less prominent, and the funnel, which leads into the sac, can be eradicated and the sac itself removed. To do this, first divide the transversalis and internal oblique muscles, outward just above Poupart's ligament as far as its outer and middle thirds. This will give plenty of room in which to manipulate the sac and will be utilized in re-forming the internal ring. Free the neck of the sac and the peritoneum all about the internal ring. Then, while making strong traction on the sac, ligate, with chromic gut No. 2 or silk, the pedicle as high as possible and cut the sac away. This procedure fulfils two conditions. It removes the sac and obliterates the funnel leading into it.

Theoretically it would appear to be a good plan to roll up or plait the sac and leave it as a pad over the internal ring, forming a distinct projection into the abdominal cavity. Practically this pad serves as a wedge to reopen the ring until it disappears by absorption. Thus nothing is gained by retaining the sac at the time of the operation, but a fancied security is obtained and a source of possible future trouble included.

The Cord next needs most careful attention. Numerous large veins, much loose areolar tissue, thickened coverings, must be removed and a thick, vascular cord converted into a normal, firm one. All the veins but two or three, with the excess of tissue, should be removed between the ligatures. Care must be taken, however, not to injure the arteries and the vas itself, and to leave two or three veins to carry on the return circulation.

Halsted deserves credit for suggesting this diminution in the size of the cord.

The next thing in which nature is to be imitated is in the re-formation of the inguinal canal and rings. This attempt is attended with difficulty diminishing with the thoroughness with which the operator has exposed the field of operation, and the care with which the preceding steps are carried out. The farther apart

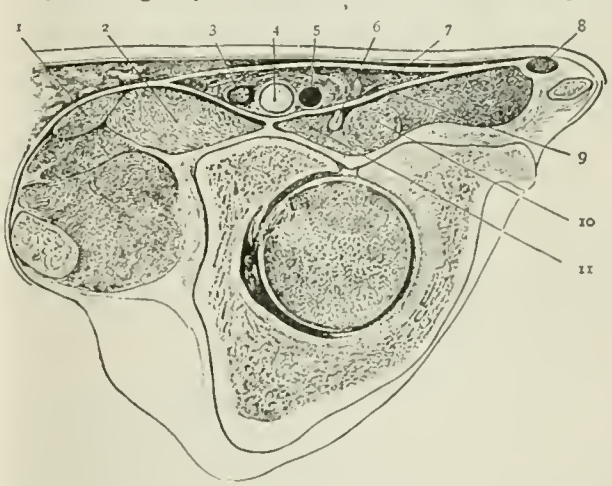

FIG. 8.—Section through the Left Femoral Canal; Upper Segment. The section runs just below and parallel with Poupart's ligament. 1, The adductor longus muscle; 2, the pectineus muscle; 3, the gland of Rosenmuller; 4, the femoral vein; 5, the femoral artery; 6, the anterior crural nerve; 7, fascia lata, the superficial layer; 8, sartorius muscle; 9, fascia lata, the deep layer; 10, the iliacus muscle; 11, the psoas major muscle.

the inguinal rings are the less liable is a hernial protrusion to occur. The external ring is fixed by different factors at the spines of the pubes; the internal, on the contrary, is a movable affair. In the normal state it lies opposite the middle of Poupart's ligament—in the abnormal, much to the inside of this. In our at-

tempt to imitate the natural construction it should be moved outward, at least as far as the outer and middle thirds of Poupart's ligament. The transversalis and internal oblique have already been divided for this purpose to this point. Now transfer the cord to the

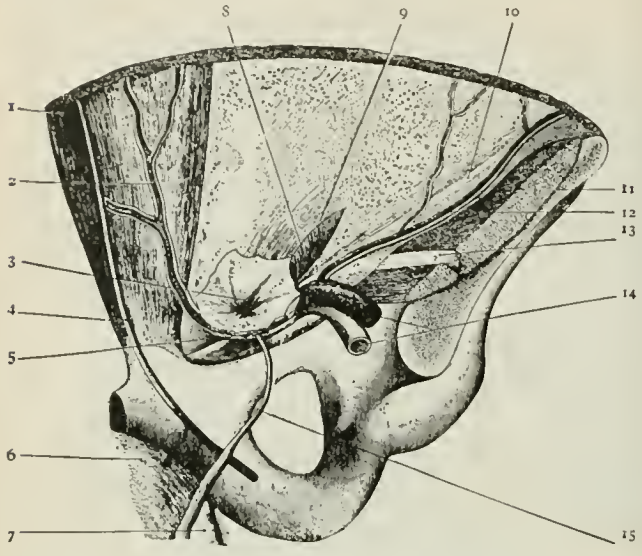

Fig. 9.—Indirect Inguinal Hernia, Showing the Relations at the Neck of the Hernial Sac. 1, The rectus muscle; 2, the deep epigastric vessels; 3, the hernial sac; 4, obliterated hypogastric artery; 5, transversalis fascia; 6, the urinary bladder; 7, tip of the seminal vessel; 8, the internal inguinal ring; 9, semilunar fold of the transversalis fascia; 10, Poupart's ligament; 11, iliacus muscle; 12, the deep circumflex iliac artery and vein; 13, the anterior crural nerve; 14, the external iliac artery and vein; 15, vas deferens.

outer angle of the incision, and while holding it there suture the transversalis and internal oblique muscles and the transversalis fascia to Poupart's ligament as advised by Bassini. Slack muscular tissue, loose conjoined tendon, even the adjoining edge of the rectus sheath can be gathered up and all sutured firmly to Poupart's ligament. Place the cord along the sutured line, and in similar manner close the aponeurosis of the external oblique over it, leaving at the spine of the pubis a small opening for the transit of the cord. The inguinal region is thus reconstructed on sound natural lines. The first line of sutures is interrupted, the second interrupted or continuous. The material is No. 1 or 2 chromic gut. The placing of the sutures at the cord is most important, as by them the inguinal rings are re-formed and will fit the cord snugly or loosely according to the nearness of the suture to the cord. The suture should be so placed that when tied the tissues will grasp the cord snugly but not constrict it.

In the Female, the conditions which allow the development of an inguinal hernia and the steps necessary for its radical cure are similar to those in the male, and the subject does not require a separate consideration. The herniæ are less frequent and are seldom as large as in the male. The operation can be done with greater ease and is more often attended with a permanent result.

Bearing on this subject is the frequency with which Alexander's operation for shortening the round ligament is followed by hernia. This undesirable result is due to a failure to reproduce the natural construction, and can be prevented by carrying out the operation on the same lines as given for a herniotomy minus the sac and contents.

Shorten the round ligament, and re-form the internal ring at the outer and middle thirds of Poupart's ligament; when closing up the inguinal canal include the round ligament in the sutures. After the external oblique has been sutured place the round ligament in the line of the skin incision, and when suturing the latter include the former. The entire inguinal region is thus re-formed; there has been secured ample room satisfactorily to shorten the round ligaments, and these have been firmly anchored by a double line of suturing, so that they cannot slip and a hernia cannot develop.

The Femoral Region and Hernia.—While herniæ do not take place at the femoral opening with the same degree of frequency that they do at the inguinal, the attempt at radical cure is attended with greater difficulties and more frequent failures.

The reasons why femoral are less frequent than inguinal herniæ, why they are four times more numerous in women than in men, and why they are more difficult to cure, are due to structural conditions. The peritoneal pouch, or femoral fossa, over the site of the femoral ring is smaller and shallower than the external inguinal, and is rendered less effective in predisposing to hernia by a packing of adipose tissue and a small lymphatic gland. When the peritoneum, fat, and gland are removed we find a well-marked pit at the inner side of the femoral vein. This is the so-called internal femoral ring. It has for its boundaries, in front and above, the inner part of Poupart's ligament; at the inside, Gimbernat's ligament; behind, Cooper's pubic ligament, and, at the outer side, the femoral vein in its sheath.

The usual description states that a membrane is found closing in this ring, the so-called septum crurale of Cloquet. Joessel, on the other hand, says there is no fascial covering between the femoral vein and Gimbernat's ligament. This space is occupied by the gland of Rosenmüller, which lies free in the upper part of the femoral canal, and the septum crurale does not exist. At this spot the intestine can pass under Poupart's ligament into the femoral canal by invaginating the parietal peritoneum without being hindered by any layer of fascia. Such a hernia passes out directly from the abdominal cavity assisted by gravity, and appears at the saphenous opening. This opening is a gap in the fascia lata for the passage, chiefly, of the internal saphe-

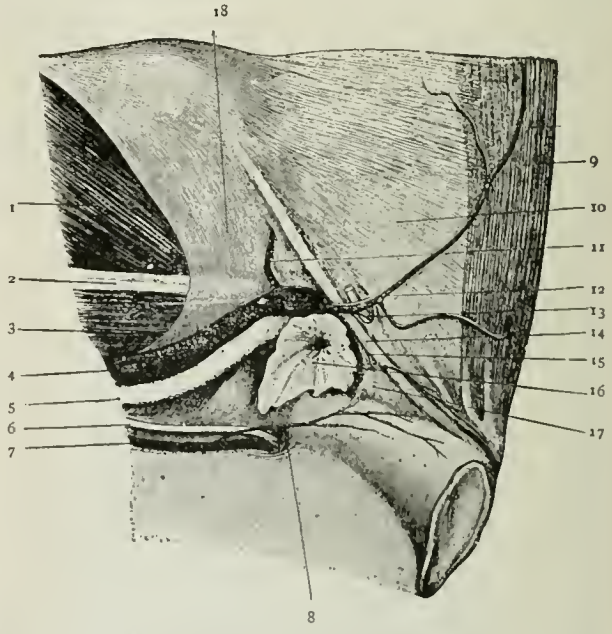

Fig. 10.—Femoral Hernia Showing the Relations about the Neck of the Sac. 1, The iliacus muscle; 2, the anterior crural nerve; 3, the psoas magnus muscle; 4, the external iliac artery; 5, the external iliac vein; 6, the obturator vein; 7, the obturator artery; 8, the pubic branch of the obturator artery; 9, the rectus muscle; 10, the transversalis fascia; 11, the deep circumflex iliac artery; 12, the deep epigastric artery; 13, the spermatic artery; 14, Poupart's ligament, 15, pubic branch of the deep epigastric artery; 16, hernial sac; 17, Gimbernat's ligament; 18, the iliac fascia.

nous vein. It is closed by the deeper layer of the superficial fascia, which, on account of perforations for numerous structures, is called the cribriform fascia. This layer is protruded before the advancing hernia and furnishes one of its coverings. The hernia now

changes its direction and enlarges forward and upward over Poupart's ligament.

The explanation of this change of direction is found in two factors. One is that the cribriform fascia is more firmly attached around the lower margin of the saphenous opening than above; a second one, and one more potent to deflect the hernia, is the presence of the superficial veins (external pudic, epigastric, and circumflex iliac), which empty separately or by a branch common to two or more into the saphenous vein just before it joins the femoral. A downward enlargement of the hernia would require that the veins be stretched or displaced. The hernia is still further assisted in its upward course by flexion of the thigh. The remaining coverings to the hernia do not interest us now.

Besides the factors indicated above which allow and even favor the occurrence of femoral hernia, there is another reason which I think is not sufficiently emphasized. It is the unavoidable presence of the large, easily compressed femoral vein alongside a distinctly weak spot in the abdominal wall. Under excessive pressure the vein can be compressed; this stretches and weakens the adjacent tissues. This stretching and yielding of the tissues will take place mostly at the inside of the vein. Furthermore, the vein does not, like the cord, traverse the different layers of the wall obliquely, but leaves at a point beneath these fixed layers and in a direct course from the abdominal cavity.

The only reason, then, why femoral herniæ are not more frequent is the small extent of this weak area.

When Poupart's ligament stretches as in the aged, male or female, or in the female after repeated pregnancies, then, one of the main supports being lost, the weak area is enlarged and a condition for the development of a femoral hernia is present. As regards the influence of sex, the broader female pelvis plus the influences of pregnancy furnish the explanation of why this form of hernia is four times more prevalent in the female than in the male.

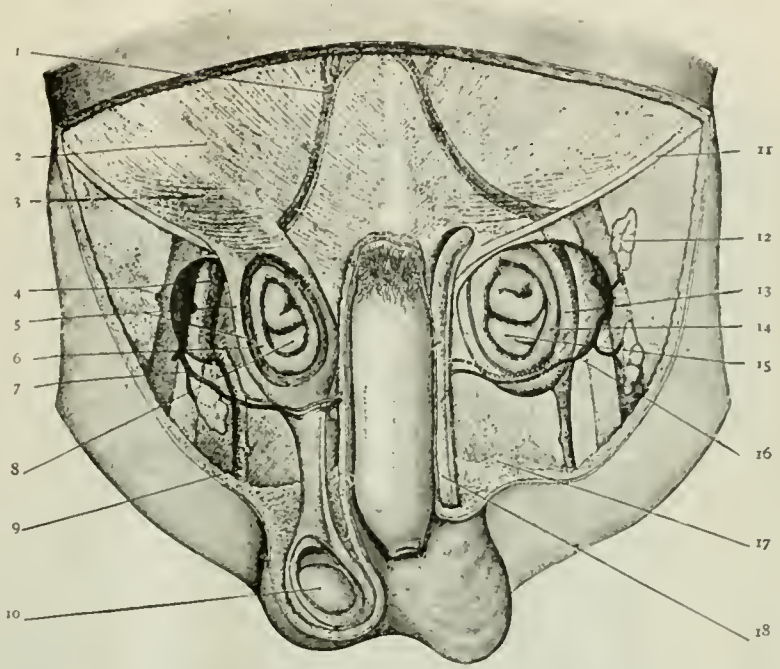

FIG. 11.—Dissection of an Inguinal and Femoral Hernia. 1, Deep epigastric vessels represented as showing through the overlying parts; 2, aponeurosis of the external oblique muscle; 3, the intercolumnar fascia; 4, femoral artery and vein; 5, fascia propria of the inguinal hernia; 6, the hernial sac; 7, the superficial external pudic artery; 8, knuckle of small intestine; 9, internal saphenous vein; 10, the testicle; 11, Poupart's ligament; 12, lymphatic glands; 13, fascia propria of the femoral hernia; 14, sac of the hernia; 15 knuckle of small intestine; 16, superficial external pudic artery; 17, fascia lata, superficial layer; 18, spermatic cord.

To summarize the architectural features which predispose to a hernia in the femoral region, we find these present:

First. The peritoneal depression, especially prominent if the usual filling of fat and Rosenmüller's lymphatic gland are absent, or Poupart's ligament is unduly lax.

Second. An open, according to Joessel, femoral ring and canal.

Third. The course of the femoral canal leading directly outward from the abdominal cavity.

Fourth. The large saphenous opening covered by the weak cribriform fascia.

Fifth, and most effective to my mind, the presence of the large compressible femoral vein.

How can such inherent and acquired weaknesses be overcome by an operation? The plans are many, some simple, some very complicated. I shall not enter at this time into a discussion of the various operations.

Theoretically, the indications are to obliterate the peritoneal fossa and close up the abnormally large ring and canal, and shorten the elongated Poupart's ligament. Practically this is much more easily said than done.

First of all, lay open the hernial tract, but do not cut through Poupart's ligament. Free, ligate, and remove the hernial sac, as in the inguinal operation. Suture Poupart's ligament to the fascia and even periosteum in front of the ilio-pectineal line, beginning as close to the femoral vein as is safe and passing inward to the spine of the pubis; then by deep sutures obliterate the femoral canal and close up the saphenous opening. Suture the skin.

This is a very simple plan, yet it fulfils all the requirements of the case as well as do the more elaborate operations; because after all has been done there remain the femoral vein and the elements of weakness its presence induces. The main point is to place the deep sutures so close to the vein that when they are tied Poupart's ligament will closely hug, but not compress, the vein, and the slack in the ligament itself is taken up.

In conclusion, then, I wish to emphasize:

First. That we should know the construction of the normal inguinal and femoral regions.

Second. That we should know the changes which take place when a hernia has occurred at either of these regions.

Third. That in attempting a radical cure we should seek to reproduce the natural construction of the parts.

Fourth. That nothing but absorbable suture materials should be used.

Fifth. That every precaution for obtaining primary union be utilized and carefully followed.

Sixth. Do not apply a truss to preserve the effects of the operation. If a radical cure has been done a truss is unnecessary; if it has not been done, a truss will not prevent the return of hernia.

Note in reference to the illustrations: Figs. 1, 2, and 3 are photographs of plaster-of-Paris casts, made by the writer, of the lower abdominal and pelvic cavities, in the following manner: The subjects were suspended vertically. A median incision was made into the peritoneal cavity from the umbilicus upward. The intestines were held upward by cords while liquid plaster was poured into the abdomen until it rose to the level of the opening, and allowed to set. The remaining figures (4–11) are from Joessel's "Anatomy."

1125 MADISON AVENUE.

LIGHT AS A REMEDIAL AGENT.

By J. W. KIME, M.D.,

FORT DODGE, IOWA.

Light has great power of penetration; it is exceeded in this respect by the Roentgen rays only. This I have been able to demonstrate by the following experiments in which I was assisted by Mr. G. L. Hostetler, a photographer of this city. The subject upon whom the experiments were to be made was taken into the dark room, and the plates were applied with great care so that all rays of light, save those that traversed the body from front to back, might be excluded.

The first illustration shows the method of photographing through the body. The direct rays of the sun, falling upon the reflector through the skylight, are focussed upon the chest of the person upon whose back has been placed the photographic plate upon which the picture is to be taken.

A transparency on glass of a valley in the Klondike region was used as the original from which the picture was to be taken. This was fastened to a photographic dry plate which had not been exposed to light, and the two were placed upon the back between the shoulder blades of the subject, a well-developed man weighing one hundred and fifty pounds, the transparency being placed next to the skin with the sensitive plate immediately behind it. Over these were placed black paper, black cotton wadding, a surgeon's plaster, and some large black cloths, and all were bound firmly down by means of long black bandages. He was then taken to the light room and the reflector was turned upon the chest for fifteen minutes. After exposure he was again taken to the dark room, and the plates were removed and the picture shown in Fig. 2 was developed on the photographic plate.

All sources of error were excluded with the greatest care, and the operation was repeated many times on various persons with like results. To test further the reliability of the procedure, and to make certain that the picture was not produced by contact of the transparency with the plate, aided by the body-heat or by some undetermined influence other than the light transmitted through the body, plates were arranged in the same manner and for like periods of time without attempting to pass light through the body, and no pictures developed upon them.

Fig. 2 represents a scene in the valley of the Klondike photographed as shown in Fig. 1.

Fig. 3 represents a picture of the Mason City and Fort Dodge depot, and in the background the Fort Dodge High School building, taken through the right hand of the writer, which is one and one-fourth inches thick. The same care was exercised in this instance as above described, and all possible sources of error were carefully excluded. Time of exposure, five minutes.

Fig. 4 was produced as a transparency from the same negative as Fig. 2, and was taken inside the cheek of the writer with the mouth tightly closed and covered with the hand. Time of exposure, five seconds.

These photographs were taken with such care and exactness that they establish the fact that the actinic rays of the sun when sufficiently concentrated may be made to pass entirely through the body of a well-developed man.

Fig. 1.

The rays of light pass through the skin with considerable difficulty; more readily through muscular tissue, and much more readily through bone. In producing a picture through the cheek the rays of light pass through but a single thickness of skin, and the picture is reproduced almost instantly. As a matter of therapeutic interest it is important to bear in mind the structures through which light must pass in reaching the deepest portions of the lungs. There are a single thickness of skin, the semi-transparent sternum and ribs, a few thin muscles, and the transparent pleura to be passed through, and then the light has reached the lungs, themselves almost wholly composed of the thin-walled air cells. Light of considerable intensity must therefore reach to the posterior thoracic walls.

The reflector used in making these experiments is a compound circular mirror thirty inches in diameter and overlaid with blue glass. It is so constructed that all the light which falls upon it is focussed upon

a spot six inches in diameter at a distance of eight feet in front of it. Thus a very powerful blue light is brought to bear upon the parts.

The heat rays of the solar spectrum are largely contained in the red band, while the actinic or chemical rays are much more abundant in the violet and ultra-violet bands; thus by utilizing the blue light we get a much greater percentage of actinic light in proportion to the heat rays than if ordinary white light be used.

The therapy of light is based upon the following principles:

1. Light is a powerful germicide, its bactericidal action being due to the violet and ultra-violet rays, or so-called chemical rays, of the solar spectrum.

2. The chemical rays of light are irritant in their action, not only upon the skin but to all the tissues through which they pass. This irritant effect is noted in erythema solare, and is often seen even in mid-winter. Very strong electric light produces similar effects. Widmark, of Stockholm, has been able to demonstrate that this dermatitis is due to chemical action and is independent of the heat rays, and that it is not a burn. In the treatment of disease by this agent the improvement may, at least in part, be due

Fig. 2.

to the irritant action arousing to greater activity the vital forces in the parts upon and through which the light is made to pass; in other words, increased phagocytosis may play an important rôle in the therapy of light.

3. The power of light to penetrate the tissues of the body. To these may be added:

4. The chemical action of the light upon the blood itself while circulating through the parts bathed in the powerful light. Sunlight must be carefully excluded from our bacteriological laboratories, otherwise many of our choicest cultures will be killed or fail to develop. If, then, light of sufficient intensity may be made to penetrate the tissues of the body, a baneful influence will be exercised upon the growth and development of bacteria in them.

The bacillus of tuberculosis in lupus is destroyed by the action of the light. Finsen, Abrams, and the writer have reported over four hundred cases of lupus thus treated and cured. If light may be applied sufficiently strong to tuberculous deposits in other tissues of the body, there is every reason to hope that like results may follow.

I am now treating a number of cases of tuberculosis pulmonalis in the manner shown in Fig. 1, and all the patients are gaining in weight and are otherwise improving. The cases are treated twice daily, and each séance is of thirty minutes' duration.

From my records I will select the following:

Case V.—Miss M. K., aged twenty-one years, domestic; has had lupus nasi one year. The patient had previously been treated with ointments of various kinds. Her father died of lupus two years before the beginning of treatment of her case. He had lupus of the face and died as the result of an operation for its removal. On August 9, 1898, light treatment was begun, and was practised daily for half an hour until September 1st. No nodules then appearing, the treatment was discontinued. On September 20th, the ulcer was completely healed, and there has been no relapse.

Fig. 3.

Case IX.—Miss G., aged twenty-five years, has had lupus of the side of the neck for six months. The process had ulcerated deeply into the subcutaneous cellular tissue. The lesion was one and one-half inches in length by one inch in breadth. Previous treatment was by ointments of various kinds, but the ulceration had steadily progressed. Light treatment was begun April 21, 1899, and continued on each alternate day until May 5, 1899. The séances were of ten minutes each. The scabs were removed before treatment began and the ulcer was kept clean with sterile water. All nodules had disappeared by May 1st and the wound was completely healed May 25th. There has been no relapse.

Case X.—Anna K., aged thirty-six, single, domestic. The mother died at thirty of tuberculosis. Nothing is known as to the father. The present trouble began two weeks prior to the first visit. It began as a bleb the size of a ten-cent piece on the left cheek. On June 7th, the ulcer had penetrated all the layers of the skin; there were also other small ulcers which are not so deep. There was great pain in the distribution of the facial nerve owing to one of its branches being laid bare by the ulceration. Treatment was begun on June 7, 1900. Three treatments of ten minutes each, with blue lens at near cautery point, effected a cure in two weeks. There has been no relapse to date.

Five cases of lupus now under treatment are all improving.

Ordinary cases of lupus require treatment for from four to twenty weeks.

It has long been known that countries having a maximum of sunshine were most favorable to recovery from the ravages of tuberculosis. Arizona, New Mexico, California, and Colorado have been the Meccas for those suffering from this disease. It has likewise been recognized that cattle on our western plains are practically free from tuberculosis, while those confined in barns are seriously affected with it.

Fig. 4.

Sunshine has not, however, been used in the most effective manner. Patients have been sent across the continent to enjoy its advantages, but upon reaching the land of sunshine they have still enveloped their bodies in clothing impervious to light. That sunshine may be of greatest value it must fall upon the man himself and not upon his clothing. Ordinary sunshine falling upon the surface of the body penetrates

the tissues to a considerable depth. The condensed actinic rays of the sun pass entirely through the human body.

The Influence of Sodium Salicylate on General Metabolism.—Francis W. Goodbody, as the result of original investigations, concludes: (1) That sodium salicylate causes an increase in the quantity of urine excreted, and in the specific gravity; the latter increase being principally due to the increased elimination of the nitrogenous substances, especially of the urea; (2) that sodium salicylate causes an increased breaking up of proteids in the body; (3) that sodium salicylate has no influence on general metabolism, so far as the absorption of proteids and fats is concerned, in spite of its known cholagogue action.—*The Journal of Physiology*, August 29, 1900.

The Lymph Node as a Factor in Diagnosis.—C. A. Wheaton describes the physiological functions of these structures, dwelling on the fact that they are engaged in a constant warfare against systemic contamination and in the manufacture of cell elements, the duty of which is to maintain the orderly metabolism of the body. He deprecates the excessive zeal of some modern surgeons in excising enlarged cervical glands, contending that in many cases the enlargement can be removed by proper attention to bodily nutrition. He says that, with the exception of the indiscriminate castration of women, none of the operative procedures have been more fashionable than the excision of enlarged lymph nodes in the neck, and the indiscriminate application of this operation merits just as severe denunciation as the other.—*St. Paul Medical Journal*, September, 1900.

Removal of the Cervical Sympathetic Ganglia for the Relief of Exophthalmic Goitre; with the Report of a Case.—M. F. Coomes, after some remarks on the nature of Graves' disease, states that he operated on April 7, 1900, upon a colored woman, twenty-nine years of age, removing the three cervical sympathetic ganglia on the right side. This was a most typical case, and had existed two years, receiving the ordinary treatment at the hands of different physicians. Her temperature preceding the operation was 101° F.; the average pulse rate, 140. The temperature and pulse records show that after the operation her temperature went down below 100° F., and the third day after the operation the pulse rate fluctuated, being 110 on April 19th, when she was discharged from the hospital, and that the temperature was normal, with the exception of two or three days, when it was up a degree or two, as a result of irritation of the wound. There was no suppuration whatever in connection with this operation; all the unpleasant symptoms gradually decreased; there was a decided improvement in the exophthalmos, the eyes receding very perceptibly; the excessive nervousness disappeared almost entirely, her sleep becoming peaceful, and there has been a decided increase in her bodily weight—a very great contrast to her restless condition preceding the operation.—*American Practitioner and News*, August 15, 1900.

Atriplicism.—Under this heading A. Boddaert calls attention to an article by Matignon, who saw service in China at the time of the late war with Japan. The cases reported by the latter writer occurred during the famine subsequent to the war. They consisted of a group of cases due apparently to the ingestion of the sprouts of the orach or chenopodium (family Atriplex). This is a vegetable growth especially preferred by the Chinese, who prepare it in several different ways and under usual circumstances do not seem to suffer any ill effects from eating it. Matignon saw, however, cases in which its ingestion was followed by paræsthesic sensations in the thumb, gradually followed by swelling extending up the arm, and later involving the face, making the patient look like a case of scarlatinal nephritis. This stage was followed by a subsidence of the infiltration and the occurrence of large phlyctenulæ containing a sero-purulent fluid and leaving ulcerated surfaces, finally these cicatrized and were succeeded by large, exuberant cheloid masses. It does not appear that the condition has ever resulted fatally.—*Bulletin de la Société de Médecine de Gand*, July, 1900.

The Use of Gold Wire in the Radical Operation for Inguinal Hernia.—Gaspare Fiore advocates the use of gold wire which is extremely fine, strong, and flexible. So far it has been used on seven patients, with the best possible results. For ligature of the neck of the sac, a wire with the diameter of m. 0.0065 was used, while for suture of the triple layers m. 0.0011 was found to be better. The wires were sterilized by being boiled in water for several minutes.—*La Riforma Medica*, August 28, 1900

Severe Case of Poisoning from Black Varnish on Boots of Yellow Leather.—A. Hallipré and Bellicaud give an account of a patient who during the funeral services of a relative was seized with serious symptoms of poisoning, viz., asphyxia, blueness of extremities, lips, nose, and tongue, coldness of extremities, drowsiness, accelerated respiration (32), feeble pulse (90). Treatment consisted of injections of caffeine and ether, sinapisms, friction with alcohol, bleeding, injection of serum, inspiration of oxygen, potions of ether and ammonium acetate. Recovery followed. The cause of the poisoning was traced to the patient's boots, which had been newly varnished with aniline black. The patient had found the odor of the varnish very unpleasant and oppressive. An analysis of the varnish proved the presence of an aniline oil.—*La Revue Médicale de Normandie*, August 25, 1900.

Physiology of Voice Production.—In a general article on this subject M. A. Goldstein concludes as follows: (1) All elements carefully considered, the best form of breathing applicable to voice production and singing is the rational combination of the costal with the diaphragmatic type. Reserve force in breathing is best attained by deep inspiration, fixation of the distended diaphragm and thorax, and control of these muscles while tone is produced. (2) To facilitate vocalization, the larynx should never be tightly contracted by the muscles of the throat, especially in the production of the upper registers. (3) On the resonating cavities, their proper conformation and position in relation to the vibrating cords and larynx, depend the quality and timbre of the voice, and the careful and proper placing of tones is perhaps the most essential factor in voice production.—*Medical Fortnightly*, September 15, 1900.

The Pathogenesis of Icterus.—Browicz comes to the following conclusions: (1) The occurrence of jaundice primarily depends on the increased activity of normal liver cells, which through various stimuli may be caused to take up unduly large amounts of nutritive material and hæmoglobin, and so produce an increased quantity of bile and bile pigment. (2) Only a healthy, normally functionating liver cell which has absorbed and converted an excess of nutritive material, and therefore produced an increased amount of bile, is able wholly to dispose of this excess through the intracellular bile passages: therefore bile reaches the circulation through the walls of the capillaries. (3) Mechanical conditions have but

an unimportant part in the causation of jaundice through the production of intra-acinous circulatory disturbances in the capillaries. (4) The path of the bile in reaching the blood lies through the blood capillaries of the hepatic acini, and only to a moderate degree involves the lymph-vessels of the larger bile passages. (5) All forms of jaundice are explicable on these grounds, viz., an increased activity of the liver cells and a concomitant overproduction of bile and bile pigment.—*Wiener klinische Wochenschrift*, August 30, 1900.

A Case of Typhoid Fever Treated by the So-Called "Woodbridge Treatment."—A. Schmidt recently treated a man who was in the sixth day of the fever when first seen. The case was rather a severe one when treatment was begun, the nervous symptoms with headache being marked. The usual Woodbridge tablets were given and a diet allowed of milk, eggs, and rice with a moderate amount of alcohol. The patient was convalescent on the thirteenth day of treatment, on the fourth day of which the temperature fell to normal and did not rise again.—*Montreal Medical Journal*, August, 1900.

Perforation of the Fœtal Skull intra Partum, with Favorable Outcome.—L. Pernice reports the following case: Owing to almost complete absence of labor pains and an apparently contracted pelvis the presenting vertex was perforated with the instrument of Naegele. An abundance of bloody fluid mixed with what appeared to be brain matter came away, the forceps was applied, and the child was delivered without further trouble. As it still breathed, an antiseptic dressing was applied to the wound as a matter of form, with the result that the child lived and a complete hemiplegia existing at birth also entirely subsided. At present the child is one and three-fourths years of age, and is mentally and physically normal except for a large cerebral hernia over the occiput.—*Centralblatt für Gynäkologie*, September 1, 1900.

Apparent Death in the New-Born.—B. S. Schultze directs that the cord should not be cut if the apparently asphyxiated infant is bluish-red in color and muscle tonus is still present. Aspirated matter should be removed from the mouth and cutaneous stimuli applied. If no reaction follows, the cord should be cut and the child dipped momentarily into cold and then warm water, repeating until a loud cry results. If the child is pale and limp like a corpse, useless time would be lost in trying to produce reflex excitability. The cord must be cut, the mouth cleansed, the root of the tongue pressed forward to raise the epiglottis, and artificial respiration should be performed by the Ewing method. Eight to ten inspiratory and expiratory movements are then to be made and then a warm bath should be given. If no result follows the swinging should be repeated. After the first spontaneous inspiration which usually follows the end of the expiratory swing, the child is placed in the warm bath; if respiration is superficial it should be plunged into cold water.—*Wiener medizinische Blätter*, August 30, 1900.

Spurious Meningocele.—Joseph Sailer describes under this name a condition in which there is defect in the skull produced by some injury; through this defect cerebro-spinal fluid passes to and accumulates on the outer side of the skull beneath the pericranium that has been elevated by its force. The symptoms are: first, the tumor, which fluctuates, pulsates, and occasionally upon auscultation gives a harsh murmur, and the signs of injury to the brain—that is, vomiting, alterations in character, convulsions, and paresis. A curious murmur has been heard in some cases, the nature of which it is hard to understand. It is synchronous with the pulse, loud and hard, resembling that of an aneurism. The nervous symptoms vary according to the nature of the brain injury. In a surprisingly large number of cases they are absent, and epilepsy seems much less frequent than after simple fractures. The treatment, now that infection can be avoided, should always be operative. There is practically no danger, and in recent cases the likelihood of perfect cure is very great.—*University Medical Magazine*, September, 1900.

Peri-Tonsillar Abscess in Children.—L. T. Royster reports a case of this affection, which is rare in childhood, occurring in only three per cent. of this class of patients. It occurs as a local infection, consequent upon acute catarrhal inflammation of the pharynx, upon the acute infectious diseases, and also rarely as a complication of retro-pharyngeal abscess. The micro-organism is usually the staphylococcus. The general symptoms resemble those of acute follicular tonsillitis, but the temperature is lower and depression less marked. The local symptoms differ: there is great pain on swallowing, torticollis is common, and a fixed lower jaw is almost invariable. The pain complained of is more marked than the examination can account for. By palpation the unilateral induration can usually be detected. The danger in severe cases comes from œdema (rarely fatal), spontaneous rupture and perforation of an artery. Vertical incision of the most prominent joint, with drainage of the cavity, is the only treatment.—*Pediatrics*, September 15, 1900.

Operation without Digital Contact with the Wound.—König believes that the surest way to secure asepsis of the wound lies, not in the sterilization of the hand nor in the use of gloves or varnishes, which means, necessary as they are, still cannot help being inadequate, but in a persistent effort to avoid touching the wound with the fingers at all. By trial he has found it perfectly feasible to do such operations as joint resections, osteoplastic operations, and in fact most of the commoner surgical procedures on the extremities, without touching the tissues otherwise than with instruments. The abdominal cavity, indeed, is a field where digital manipulation will always be a necessity, but even here, with practice and suitable modifications of the armamentarium, much may be accomplished without actual contact. The assistants as well as the operator should be trained to avoid manipulation of the operative field, and with an abundance of especially long and variously shaped retractors, forceps, etc., may perform nearly all their functions from a distance.—*Centralblatt für Chirurgie*, September 8, 1900.

The Treatment of Sciatica.—A. Heym says that in acute sciatica bed and warmth often relieve the pains with surprising rapidity. The patient's knees must be bent. The latest and best remedy is freezing the skin by means of methyl chloride or ethyl chloride. This works best in thin persons, but often fails in the corpulent. In chronic sciatica, rest in bed is not to be recommended, but a certain amount of exercise is necessary, the affected leg being, however, protected from all exertion. The best treatments consist of electro-therapeutics with the constant current; hydrotherapeutics, principally steam or hot-air baths; massage, and Swedish movements. If all these remedies have been tried without success, nerve extension may be tried, but the percentage of cases resulting in cure in this way is very small.—*The Chicago Clinic*, September, 1900.

The Use of Morphine in Surgical Practice.—Edward Martin says the general indications as to the

employment of morphine in surgery may be summarized as follows: (1) Morphine should be given hypodermically and in doses sufficient to accomplish the purpose for which it is given. (2) When surgical shock is attended by such severe pain as to cause uncontrollable restlessness, morphine should be given in doses adequate to relieve it. The same treatment is indicated for shock-restlessness without pain (usually due to hemorrhage), the appropriate general treatment for shock being also carried out. (3) Morphine is the best internal hæmostatic in the treatment of hemorrhage. When the hemorrhage is complicated by restlessness, morphine is absolutely indicated because of its quieting effect upon both mind and body. (4) When drunkards, or exceptionally neurotic patients, are to be anæsthetized a preliminary hypodermic injection of morphine renders such anæsthetization quicker, easier, and safer, and favorably affects the stage of recovery. Obstinate and exhausting vomiting after ether is sometimes relieved by morphine. (5) If in the first twenty-four hours after operation pain becomes so severe as to cause uncontrollable restlessness, this pain should be relieved by morphine. To this rule there are practically no exceptions; it applies to all operations regardless of the operative area. (6) When used in accordance with these indications the beneficial effects of morphine so overshadow its injurious effects that the latter are not demonstrable. To this rule there may be a very few exceptions.—*Therapeutic Gazette*, September 15, 1900.

Antagonism between Cocaine and Hypnotics.—Carlo Gioffredi concludes from a long series of experiments: (1) That chloral hydrate is a decided antagonist of cocaine, being able to counteract the action of doubly lethal doses given to a dog; (2) other hypnotics, such as paraldehyde, are likewise antagonistic to cocaine; (3) the antagonism is complete, influencing all the important organic functions; (4) it is a one-sided antagonism, for cocaine does not counteract poisoning by the hypnotics; (5) the antagonism is a mechanical one, similar to the antagonism between the hypnotics and strychnine.—*Giornale Internazionale delle Scienze Mediche*, August 31, 1900.

On the Physiological Action of Senecio Jacobæ.—J. L. Bunch, by experimenting on dogs with preparations from the entire plant, found that intravenous injection produced a slight rise in general blood pressure and diminution in the magnitude of both auricular and ventricular contractions. There are two substances of distinct physiological action in the plant. Intravenous injection of a watery extract of the residue on evaporation of an alcoholic solution caused a marked fall of blood pressure followed by a slight rise due to constriction of peripheral vessels. The two substances have not been separated. The substance which causes a rise of blood pressure is not contained in watery extracts.—*Therapeutic Gazette*, September 15, 1900.

The Crises of Development.—Walter R. Jordan speaks of the periods of birth, dentition, and puberty as difficult passes from one tract of mountainous country to another, with a minor crisis during the stage of childhood at seven years. The author urges the young physician in his first months or years of comparative leisure to take up child study—the scientific observation of children. Such study would give a more thorough grasp of the meaning of the developmental period of life, with its peculiar susceptibility to damage, not only throughout, but accentuated at special crises; would throw light on the after-effects of the specific and other diseases in childhood; would give greater precision and force to the physician's directions as to the general hygiene of the growing child, hours on work, play, and sleep. It would be a guiding influence on all therapeutic measures adopted in cases in which development was not proceeding normally. It would introduce system into his estimation of the defects of backward children, and would supply clews to the meaning of the behavior of precocious and unsatisfactory children. It would, when previous personal or family history supplied facts, justify him in making predictions as to the future physical and mental development of particular children; it would thus give him opportunities of instituting preventive measures against developmental failure of body and mind.—*The Birmingham Medical Review*, September, 1900.

An Unusual Symptom of Perforative Appendicitis.—David Owen Thomas reports a case, the chief features of which he sums up as follows: (1) The perforation, which took place very early, was preceded by the history of pain. Ulceration probably had been going on without any rise of temperature. (2) The severity of the pain, tenderness, and rigidity of the abdominal wall were better guides than pulse and temperature, and indicated that operation was necessary. (3) Pain in the penis was so extreme that the boy was fairly beside himself—rolling and tossing around in a desperate manner, this special symptom overshadowing all others for nearly half an hour. (4) If perforation had not been promptly recognized the amelioration of the symptoms by the next day might have caused postponement of the operation and perhaps loss of the patient. The author has known this same chief symptom to occur in the perforation of typhoid ulcer. It is probable that in such cases, as well as in this case of appendicitis, pain is transferred through the hypogastric plexus to the penis.—*The Medical Dial*, September, 1900.

The Relation of Diseases of the Eye to those of the Teeth.—N. Weill states that this phase of medicine and dentistry belongs to the newer time. Pathological conditions of the eye or orbit can cause dental disturbances, and vice versa, either reflexly or by continuity, those of the latter group being less frequent but graver. Very serious may be the results of abcesses of the orbit, which may be primary or secondary in origin. When of dental origin they may arise in one of two ways: either via the periosteum of the superior maxillary bone and the orbit, or via the antrum of Highmore. Timely operation is demanded. The writer is unable to find any case recorded in which an ocular or orbital affection involved the teeth by continuity. The reflex currents can originate in the eye and manifest themselves by pain in the teeth, but the reverse neuroses, *i.e.*, the teeth the cause of the eye disturbance, are probably more frequent. The writer cites numerous cases in illustration of this subject.—*Pennsylvania Medical Journal*, September, 1900.

Purpura Rheumatica.—M. A. Bliss reports the case of a boy aged six years. Red spots appeared on the dorsum of the hands and feet, and on both aspects of the arms and legs. They multiplied rapidly and extended up the thighs and over the upper arms, this increase being accompanied by an extensive urticaria. The right knee and left elbow joints were the seat of stiffness, swelling, and soreness, but no redness. This joint involvement would recur every evening about five o'clock, disappearing over night. By the ninth day the skin was free from purpuric spots, but a slight stiffness still recurred in the joints. Two months previously the child had suffered from malaria, so that on the appearance of the purpuric spots the writer administered quinine. The pigmented form of the malarial plasmodium was found in the blood. The author thinks there is a possibility that the purpura was due to the malarial infection.—*St. Louis Courier of Medicine*, September, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, October 13, 1900.

CORNING'S METHOD OF MEDULLARY NARCOSIS.

THE value of recording original observations as soon as made and prospecting their adaptability to given ends is well shown in the matter of spinal cocainization concerning which so much is being written and said.

Although fully fifteen years have elapsed since Dr. J. Leonard Corning of this city published his experiments on this subject, and notwithstanding it is only within a few months that his suggestions have been followed, no one can question his claims to priority in first calling attention to a method of anæsthesia which is now challenging a trial by numerous surgeons here and abroad.

As the real one who first established the principle of the action of cocaine upon the cord and who first demonstrated its practicability not only by actual trials upon the lower animals, but by using it for anæsthetic purposes upon the human subject, his name must necessarily be associated with that particular field of work, however it may be extended by other investigators.

While it is well proven that the anæsthesia is perfect so far as it goes, the question of the hour which would naturally suggest itself bears upon the possibility of safely extending the area of absolute insensibility to the upper portions of the body. The cauda equina, which is the particular part exposed to the influence of the drug, although within the spinal canal, is not, physiologically speaking, the spinal cord. What may be done with comparative impunity to a bundle of nerves may be exceedingly dangerous to attempt with a distinct motor or sensory centre. Particularly must this be the case when any portion of the cord in the neighborhood of the centre of a vital organ is cocainized. Thus it is very reasonable to suppose that injections higher up in the canal for purposes of anæsthetizing the chest regions, neck, and upper extremities are presumably very dangerous.

From such a point of view the many enthusiasts who are practising the method with a desire to extend its usefulness are in great danger of going too far. Particularly is this the case with the dosage of the drug, as many surgeons have taken great risks by injecting very strong solutions—some of them containing as much as six grains—while the standard is generally placed as two per cent. of cocaine.

It must also be recollected in such a connection that cocaine is sometimes very treacherous in its action and that a large dose in a place beyond the reach of counteracting influences may leave the ruthless experimenter entirely at the mercy of a serious and preventable accident.

The extreme aseptic precautions that must be taken in making the injection cannot be too strongly urged. For the surgeon of to-day, trained to the high art of absolute cleanliness of instruments, hands, and operation area, no lesson or suggestion is needed, but the novice is extremely liable to do great mischief. The apparent simplicity of the manœuvre constitutes its greatest danger in the hands of the tyro. Fortunately so far no serious mishaps have occurred, neither have any deaths been reported from over-dosage, but it is quite plain at this stage of the investigation that we must proceed slowly and carefully if we would prevent accidents.

While this new form of anæsthesia in certain ways lessens some of the well-known dangers of ether and chloroform administrations, it is still a question if the preservation of the mental faculties during the terrible ordeal of a severe and prolonged surgical operation is especially desirable in itself. With most persons unaccustomed to the experience the mere sight of blood, and more especially mutilation in any form, causes faintness and other forms of mental shock. Certainly such an element is not a requisite addition to the physical strain of the operation itself. In fact in some of the recorded cases the mere expectation of pain, even without its ultimate realization, appears to have had a marked depressing effect upon the vital energies of the victim. Psychologically and æsthetically this claimed advantage of spinal anæsthesia is hardly to be advocated on the score of its demonstrated utility.

It must be admitted, however, on the other hand, that the well-founded prejudice against loss of consciousness in general anæsthesia is thus effectually overruled and that the patient not only escapes the dangers of the helplessly stupefied state, but is saved many of the disagreeable and ofttimes distressing phenomena attending its preliminary induction. There may also be occasions during an operation in which conditions warranting more severe procedures than were at first expected may require the consent of the patient before going further, and this being possible may save both him and the operator much subsequent trouble. Even under such circumstances it is not necessary that the patient actually sees or hears what is going on, it being sufficient only that he has the privilege of expressing an opinion and being a party to a very important contract. Hence most operators deem it best to blindfold the patient and plug his ears in order to eliminate all the objectionable elements of the direct mental shock in question.

DEGENERATES IN THE ARMY.

DR. CHARLES E. WOODRUFF, U.S.A., in the *American Journal of Insanity*, July, 1900, contributes an instructive article on the above subject. His position, of course, qualifies him to speak with authority, that is,

so far as army degenerates are concerned. As might be supposed, however, the field of observation of this type of human beings is considerably restricted, as slight deviations from normal development are sufficient cause for rejection of candidates for the army. Nevertheless it seems that a certain number of men with some psychical stigmata contrive to pass the required examination and become soldiers. Dr. Woodruff would appear to be somewhat in agreement with the views of Nordau that a markedly high type of intelligence as well as a distinctly low type is abnormal and evidence of an unstable development. He says: "It must not be forgotten that the man who represents a strict average in every respect is an absolutely characterless individual in that he has no marked characteristics. His intelligence is quite limited, for the mean between the imbecile and the genius is a man of very ordinary ability. Soldiers with average bodies have average brains, and, though strictly normal, have not a high grade of intelligence." And again: "The moral sense, also, being nothing more than the resultant of all the higher intellectual faculties, is of average development among soldiers. Extremes are very rare, whether ideal morality on the one side, or crime on the other." Perhaps the argument that an average man physically is also an average man mentally is a sound one, but if this is so will it be contended further that a magnificent animal specimen of humanity is also as a rule endowed with a superabundance of brains? By an average man, however, probably Dr. Woodruff means one with no anomalies or stigmata. Certain it is that men of what is called genius differ from other men, and it may be that they must be classed among the large and increasing army of degenerates. The best position to hold in the order of brain power would appear to be between the average individual and the man of genius. Dr. Woodruff gives some brief studies of deserters from the army who came under his notice, and who were one and all of abnormal development.

ISOLATION OF TUBERCULOUS PATIENTS IN HOSPITALS FOR THE INSANE.

By reason of his lowered resistance, of the confinement and inactivity that his treatment often entails, of his association with numbers of other individuals, and of his indifference to and neglect of ordinary hygienic observances, in addition to the usual causative influences, the insane patient is especially liable to infection with tuberculosis. While this disease is responsible for one-seventh of the deaths due to all causes in the community, the proportion is much larger in many hospitals for the insane. According to a collective investigation undertaken by Harrington (*American Journal of Insanity*, vol. lvii., No. 1, p. 257) it has been found that the total number of deaths for the five years ending 1899, in sixty-seven State hospitals for the insane in the United States, was eighteen thousand five hundred and thirteen, of which number two thousand seven hundred and forty (14.8 per cent.) were due to tuberculosis. Dividing the hospitals into groups in accordance with their geographical situation, it appeared that the total number of deaths in institutions in the New England States was three thousand two hundred and eight, of which three hundred and eighty-three (11.9 per cent.) were due to tuberculosis; the total number in institutions in the Middle States was four thousand four hundred and ninety-four, of which six hundred and eleven (13.5 per cent.) were due to tuberculosis; the total number in institutions in the Western and Southwestern States was eight thousand eight hundred and fifty-three, of which one thousand three hundred and fifty-three (15.2 per cent.) were due to tuberculosis; and the total number in institutions in the Southern States was one thousand nine hundred and fifty-eight, of which three hundred and ninety-three (20 per cent.) were due to tuberculosis. Inasmuch as the figures obtained are not complete, conclusions based upon them as to the geographic prevalence of tuberculosis in hospitals for the insane cannot be wholly relied upon. A much more important fact, however, is developed by the investigation, namely, that while in thirty-three hospitals the percentage of deaths from tuberculosis was less than fifteen per cent., it varied from fifteen to sixty-five per cent. in the remaining thirty-four. In view of all the facts, there seems to be especially good reason and urgent need to isolate cases of tuberculosis in hospitals for the insane. Some efforts have already been made in this direction, and these can be most warmly encouraged and advantageously extended. It is the duty of preventive medicine, in restricting the dissemination of communicable diseases, ever to insist on the principles of a rational prophylaxis, namely, isolation and disinfection.

THE PATHOGENESIS OF GOUT.

It is better to confess ignorance than to assume false knowledge. In spite of the careful study that has been given to the subject of gout, it must be admitted that we are as yet uninformed as to its exact nature. That it is a disorder of metabolism is obvious, but in what manner it is brought about has not been made perfectly clear. The tendency or the predisposition to the affection may be transmitted by heredity, so that one must think of some inherent peculiarity in cellular activity, giving rise to disturbances in the internal chemistry, with the accumulation in the system of the immature products, especially of proteid metabolism. In an interesting communication presented to the Section of Internal Pathology at the recent International Medical Congress held at Paris, Sir Dyce Duckworth (*Lancet*, August 25, 1900, p. 571) expressed the opinion that gout is a morbid condition dependent upon an inherent vice of nutrition, which is manifested by imperfect metabolism in various organs or parts of the body, presumably in the kidneys and probably in the liver. This trophic disorder or inadequacy leads to the formation of uric acid, probably in excess, and to its periodic retention in the blood. Histologic study throws no light upon the intimate nature of this defect, which thus relates to

cellular potentiality, possibly under neurotrophic influence and not, so far as is known, to structural alteration. This textural disability, or a tendency to it, may be primarily acquired, and also transmitted as a fault, thereby inducing from time to time urichæmia, with gouty manifestations, in the descendants. In most instances, under conditions that provoke it, and in some cases independently of these, attacks of gout may grow up and come to a crisis. Such crises are attended with an alteration in the solubility of the uratic salt in the blood, whereby irritating crystals of sodium biurate are produced, and precipitated in various parts of the body. The paroxysm of gout, the sites of its occurrence, and its metastases are thought to be determined by nervous influences, probably dominated from a bulbar centre, and the local attacks involve either the joints or textures that have been weakened or rendered vulnerable by impaired nutrition, owing to past injury or overuse. This central neurosis is considered an essential and transmissible feature in the pathogenesis of gout, and pertains to the arthritic diathesis generally. The urichæmia of gout is peculiar and unlike that which is induced by other morbid conditions, but the occurrence of urichæmia in the gouty is by itself inadequate to induce attacks of gout. Uratic deposits in any parts of the body may be removed in course of time, but are likely to be permanent in the least vascular tissues. Uratic deposits may take place to an enormous extent in gouty persons without the occurrence of pain or paroxysms. The clinical features of gout indicate that both chemical changes (due to inherent morbid tissue-metabolism) and a neurotrophic disturbance act as pathogenic factors, and that consequently gout is to be regarded as a neurohumeral malady.

News of the Week.

The New York State Hospital for Consumptives.—The commission appointed to select a site for the State Hospital for Consumptives has examined twenty-six different places, and has finally selected one on Lake Clear, about two miles south of Upper Saint Regis Lake in the Adirondacks. The site, which includes a tract of about five hundred acres, is readily accessible by rail from all parts of the State. The site has been objected to because of the comparatively large rainfall in this region, but the soil is sandy and quickly absorbs moisture, and experience has shown that the climate is a favorable one for the treatment of tuberculosis, for it is practically the same as that of the entire Adirondack lake region. Saranac Inn is only some three miles southwest of Lake Clear. The purchase price of the tract is about $8,000. It is not yet certain that the land will be acquired, as it is said the law forbids the securing of any land in that region by the State except for forestry preserves.

Intelligence in Proportion to Size.—The Society for Child Study has been making some investigations in Chicago schools, the results of which are rather interesting. Some seven thousand pupils of various ages were examined, and taking those of the same age for comparison, the results showed that small children on an average are not so bright as children physically larger. The examinations which led to these conclusions were held in schools where there was the largest proportion of pupils descended from American-born parents. The average height of pupils twelve years old, who were in the second grade, was four feet four and three-tenths inches, while the twelve-year-old pupils in the eighth grade averaged five inches taller. The same rule was found to hold good in the examination of children of all other grades.

Dr. James P. Glynn has been appointed associate surgeon to St. Mary's Hospital, Brooklyn.

An Unusual Cause of Death.—It is reported in the papers that one of the contestants in a sword duel fought last week in France was killed by a sword-thrust through the lungs. Death occurring as the result of a French duel is rare enough to be worthy of record.

The August Mortality.—The monthly bulletin of the New York State board of health, recently issued, shows that during the month of August 11,047 deaths occurred, which is almost the average, and is a decrease of 600 from the reported mortality of July. The death rate was 18.5, against 19 5 in July. No cases of smallpox have been reported in the State since July.

Memorial Hospital at Oneonta.—The corner stone of the Aurelia Osborn Fox Memorial Hospital at Oneonta, N. Y., was laid with Masonic ceremonies on October 5th. The hospital, which is designed to be a beautiful structure erected according to the most approved sanitary and scientific plans, is the gift of Mr. Reuben L. Fox, in memory of his wife.

The Medical Society of the Missouri Valley held its annual meeting at Council Bluffs, Ia., September 20th. The society voted to contribute $25 to the Rush monument fund, and a resolution was adopted providing for a banquet after each meeting. The following officers were elected: *President*, Dr. V. L. Treynor, of Council Bluffs, Ia.; *First Vice-President*, Dr. B. B. Davis, of Omaha, Neb.; *Second Vice-President*, Dr. E. E. Sampson, of Creston; *Treasurer*, Dr. T. B. Lacey, of Council Bluffs, Ia.; *Secretary*, Dr. Charles Wood Fassett, of St. Joseph, Mo. The next meeting will be in March, 1901, at Omaha.

Alvarenga Prize of the College of Physicians of Philadelphia.—The next award of the Alvarenga prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about $180, will be made on July 14, 1901, provided that an essay deemed by the committee of award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by the secretary of the college on or before May 1, 1901. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the

motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award. The Alvarenga Prize for 1900 has been awarded to Dr. David De Beck, of Cincinnati, Ohio, for his essay entitled: "Malarial Diseases of the Eye."

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending October 5, 1900. September 28th.—Surgeon J. C. Byrnes detached from the *Massachusetts* October 1st, and ordered to the New York navy yard. September 30th.—Medical Inspector J. R. Waggener detached from duty at naval hospital, Yokohama, Japan, and ordered to duty in charge of the naval hospital, Cavite, P. I.; Assistant Surgeon B. L. Wright detached from the *Isla de Luzon* and ordered to the naval hospital, Cavite, P. I. October 2d.—Passed Assistant Surgeon L. L. von Wedekind detached from the *Richmond* and ordered to the Puget Sound naval station; Passed Assistant Surgeon R. S. Blakemen detached from the naval training-station, Newport, R. I., and ordered to temporary duty on the *Pensacola;* Passed Assistant Surgeon J. F. Leys ordered to the naval hospital, Newport, R. I., for duty; Passed Assistant Surgeon J. M. Moore detached from the naval recruiting rendezvous, Chicago, Ill., October 8th, and ordered home and to wait orders; Passed Assistant Surgeon W. F. Arnold ordered to the naval recruiting rendezvous, Chicago, Ill., October 8th; Assistant Surgeon C. R. Burr detached from the Puget Sound naval station and ordered to proceed home and to be ready for orders to sea duty; Surgeon S. H. Dickson detached from the Washington navy yard and ordered to duty at the headquarters of the marine corps, Washington, D. C.; Surgeon C. G. Herndon detached from the naval museum of hygiene, Washington, D. C., October 8th, and ordered to duty at the Washington navy yard; Surgeon E. H. Green detached from duty at the headquarters of the marine corps, Washington, D. C., and ordered to wait orders. October 4th.—Surgeon E. H. Green ordered to the *Alabama* October 16th. October 5th.—Assistant Surgeon T. M. Lippitt detached from the *Monocacy* and ordered to the naval hospital, Yokohama, Japan, for treatment.

Yellow Fever in Havana.—Reports from Havana state that the yellow-fever situation there shows no sign of improvement. During the month of September two hundred and fifty-seven cases were officially reported, with a mortality of twenty-five per cent. Eighty-four cases were under treatment on September 30th, and twenty-eight new cases were reported on the first two days of October. There is some discussion regarding the diagnosis of the disease, and many cases which some competent authorities regard as yellow fever are not reported because of the absence of albuminuria. There are not many cases among the United States troops, but there has been some alarm occasioned by an unusual prevalence of yellow fever among civilian employees of the government of occupation.

The Plague.—A death from this disease has occurred at Cardiff, Wales. The victim was a sailor who recently arrived on the *Tyne* from Rosario, Argentina. Another case of plague came to light in Glasgow on October 6th, in a part of the city which has hitherto been free from the disease.

The Biennial Congress of Scandinavian Physicians met recently in Copenhagen. It was voted to publish a report of the proceedings in the *Nordisk Medicinisk Archiv* in the German language, as it was said that papers and abstracts published in French or English were more or less neglected by the foreign press, while those in German were much more likely to receive notice. The next congress will be held in 1902 at Helsingfors under the presidency of Professor Runeberg.

The New York State Medical Association will hold its seventeenth annual meeting at the Academy of Medicine in this city on October 15th, 16th, 17th, and 18th, under the presidency of Dr. E. D. Ferguson, of Troy. The other officers are: *Vice-Presidents*, Charles H. Glidden, of Little Falls, John M. Farrington, of Binghamton, William H. Thornton, of Buffalo, and Julius C. Bierwirth, of Brooklyn; *Secretary*, M. Christopher O'Brien, of New York; *Treasurer*, Edward H. Squibb, of Brooklyn. Dr. T. H. Wiggin is chairman of the committee of arrangements.

Sanatoria for Tuberculosis at Fort Stanton.—Several mutual benefit societies, including the Ancient Order of United Workmen, the Woodmen, and Odd Fellows, have requested of the government permission to erect sanatoria for consumptives in the Fort Stanton Reservation, one hundred and fifty miles south of Santa Fé, N. M. It has been suggested that the general government allot a certain tract to any or all of the States which may make application for ground upon which to erect sanatoria. There is already a government hospital there.

Obituary Notes.—Dr. William Webb Browning died at his home in Brooklyn on October 3d, of apoplexy. He was born in Metuchen, N. J., in 1852. He was graduated from Yale in 1873, with the degree of A.B., and in 1875 was graduated from the Columbia Law School with the degree of LL.B. After practising law in this city for seven years, he entered the Bellevue Medical College, from which he was graduated in 1884. In 1895 Yale College conferred upon him the honorary degree of A.M. He was professor of anatomy and of clinical orthopedics in the Long Island College Hospital, and was a member of the Kings County Medical Society and of the American Academy of Medicine.

Dr. Maria Upton Hanford, a homœopathic physician of Brooklyn, died on October 6th at the age of sixty-three years. She was a graduate of the New York Medical College and Hospital for Women in 1890, and was the wife of a practising physician of Williamsburg.

Dr. Stephen E. D. Hoornbeck died suddenly at his home in Ellenville, N. Y., on October 3d. He was born in Wawarsing Corners, N. Y., in 1844, and

was graduated from the College of Physicians and Surgeons in this city in 1865. He soon retired from the medical profession and entered business. He was appointed a member of the Eastern New York Reformatory Commission in 1894.

Progress of Medical Science.

Medical News, October 6, 1900.

The Treatment of Consumption at Home.—Joseph Eichberg states that all therapeutists in the pursuit of the specific idea seem to have lost sight of the idea that pulmonary tuberculosis in the only forms which are amenable to treatment, *i.e.*, in its chronic forms, is always either a mixed infection or a process so limited in its distribution that natural safeguards will surround the tuberculous area with an investing capsule and thus make it harmless. The treatment of consumption may be properly classified as the specific, the climatic, the dietetic, and the hygienic. It is fair to presume that the search for specifics is not yet done, nor likely to be given up, but the patient's safety probably does not lie in that direction. The most noteworthy feature in the reports of recent studies is the uniformity of success under climatic conditions the most diverse. We may safely feel that we are not of necessity bound to any climate or altitude. The patient must live out-of-doors. Next to good air we place good food, and of this there must be an abundance. The patient should be steadily encouraged to eat more than he wants. Cream and butter should be introduced into as many dishes as possible. The third feature is good rest. It is a good rule for the patient to take no exercise until there is no fever. All sources of excitement and worry should be eliminated. The patient should sleep as much as he chooses. The fourth factor is good cheer. The moral influences surrounding the patient are all-important. Medicines from the shop really do not enter as a necessary part into this plan of treatment. The various symptoms may, however, be treated by the well-known remedies. The ordinary hygienic rules should be carefully observed. All cases, even the most desperate, are suitable for this home treatment.

Internal Secretion of the Ovary.—Arthur W. Johnstone writes that retained excretions are the causes of nearly all nervous conditions, whether at the menopause or during menstrual life. There is not an iota of proof that the ovary has any other function than the manufacture of eggs. The writer believes the rule to be that if a woman's menstruation is for any reason except pregnancy delayed, she is very apt to have symptoms closely approximating those of the change of life. This being so, he is led to believe that the internal secretion of the ovary is a myth. The ovary, then, not having any kind of internal secretion, the troubles which accompany the menopause, both natural and artificial, are due to a faulty oxidation and excretion. One other cause of this condition is the intestinal infection that goes with nearly all these cases, and this allows the colon bacillus and its associates to contaminate the nitrogenous bodies with their ptomains before they are absorbed into the blood. Until we get rid of the old superstition of "ovarian influence" and similar terms which we have heard for so many centuries, the reproductive functions will never be thoroughly understood. As to the limits of conservative surgery: When an ovary and its accompanying tube can be left in a healthy condition so that their functions can be easily carried out, they should be preserved, but those dangerous experiments which result in the leaving of a scrap of one ovary in one part of the abdomen and a piece of a tube in another, or the transplantation of an ovary from one patient to another, should be condemned.

Iritis.—J. H. McCassy defines the iris as the colored membrane which separates the lens and its capsule from the cornea. The iris is the only muscular organ that is constantly immersed in liquid. Iritis furnishes from three to four per cent. of all ophthalmic cases. It is not very frequent during the first fifteen years of life and during old age. It affects men more frequently than women. Syphilis, rheumatism (articular), injury, gonorrhœa, gout, diabetes, malaria, etc., are the most frequent causes. There are three varieties: (1) Plastic; (2) serous; (3) parenchymatous. The symptoms are pain, photophobia, lacrymation, pericorneal redness, impaired mobility of the iris, exudation of inflammatory products, and disturbance of sight. Iritis should be differentiated from conjunctivitis and glaucoma. The course of this trouble may be acute, subacute, or chronic. If free dilatation of the pupil can be secured and the injury has not been too great, the prognosis is favorable. Atropine is the sheet-anchor in iritis. It is the great anodyne. Paracentesis is indicated when the tension of the eyeball is persistently and notably raised; also in large hypopyon or dotted spots upon the back of the cornea, or when the inflammation refuses to yield to milder means. In seclusion or occlusion of the pupil an iridectomy should be performed as soon as the disease becomes quiescent.

Internal Antisepsis.—By Reynold Webb Wilcox.

Neuralgia Paræsthetica.—By James J. Walsh.

The Boston Medical and Surgical Journal, Oct. 4, 1900.

Remarks upon Obscure Non-Traumatic Tumors of the Lower Abdomen Suddenly Appearing where None had Previously been Detected.—Maurice H. Richardson, in summing up the matter of the acute abdominal emergencies which constitute the greater portion of obscure and suddenly appearing tumors, says that the chief aim should be to view the whole with common sense, to consider carefully the history, weigh carefully the symptoms, to apply all reasonable methods of examination, and finally, if it is determined that intervention is necessary, to proceed to operation without unnecessary delay. In all suddenly appearing tumors of the lower abdomen, however obscure they may be, intervention is demanded if the symptoms are the least urgent. A tumor that has attributes of sudden formation, of tenderness, of hemorrhage, of profound constitutional disturbance, demands immediate intervention. Tumors, however, which do not possess the attributes of urgency may be watched, especially if the local symptoms are subsiding and if the patient's strength is returning. From their very nature, however, they all require surgical intervention sooner or later.

Case of Patent Foramen Ovale in Advanced Life.—William L. Worcester reports the case of a negro aged fifty-seven years, admitted to the hospital suffering from general paralysis. In the physical examination then made, the following condition of the heart was noted: "Apex beat in sixth interspace, under nipple; no heart sounds heard; a long, loud murmur, systolic in time, can be distinctly made out at apex." No indications of embarrassed circulation were noticed. The patient died of exhaustion from a series of convulsions. At the autopsy the heart was found to be moderately hypertrophied; the cavities, especially the right ventricle, were dilated. The valves were healthy. The foramen ovale was patent, measuring 2½ by 2 cm. in diameter. It was divided into two unequal parts by a small tendinous cord. Immediately under the right aortic semilunar valve was an opening forming a communication between the ventricles. On the side of the left ventricle it was about 1 cm. in its longest diameter; on the side of the right ventricle not more than 2 mm. in diameter. So far as could be judged from appearances, this was probably a congenital defect.

Serum Therapy in Pneumonia.—William H. Smith says that, as the question stands to-day, it may be stated that experimentally animals may be rendered immune, that their serum has protective property, and that continued investigation is doing away with some of the difficulties which previously harassed the early investigators. But the fact still remains that in dealing with the pneumococcus we are dealing with an organism capable of many variations and degrees of virulence, and that the serum obtained under such conditions must of necessity vary both in strength and character. Experimentally, antipneumococcus serum seems to be of value. Practically, that it is of any great value does not at present seem to have been demonstrated, as the reported number of cases are too few, and the series of any one observer is too small.

A Case of Inflamed Peritoneal Cyst Simulating Ovarian Cyst with Twisted Pedicle.—By Agnes C. Vietor.

New York Medical Journal, October 6, 1900.

Prevalent Errors regarding the Diagnosis and Treatment of "Eye Strain" from Various Causes.—A. L. Ranney gives his conclusions as follows: (1) All errors of refraction (manifest and latent) should be first very accurately determined, and as far as possible corrected for both distant and near points. (2) A mydriatic should be employed before suspected latent refractive errors are finally decided upon. (3) The ophthalmometer of Javal should first be employed to detect and measure corneal astigmatism. Subsequently cylindrical trial lenses should be employed to verify the instrument of Javal or to detect astigmatism of the lens. (4) Neither retinoscopy, nor trial lenses, nor the ophthalmoscope are positive and trustworthy in estimating "latent" refractive errors. The former is probably the best of the three in skilful hands; but serious errors may be made even by a competent retinoscopist. (5) A marked difference in the refraction of the two eyes should be corrected by proper lenses at all times and for all points. This is vital to good work on eye-muscles as a

preliminary step. (6) Cylindrical glasses should preferably, but not necessarily, be set in spectacle frames, in order to lessen the danger of alteration in the axis of the cylinder. (7) No glasses prescribed should ever be worn by a patient until they have been inspected and verified by the oculist who prescribed them. (8) The frames selected by the patient or optician should always be inspected by the oculist with care to guard against decentred lenses Each pupil should accurately correspond to the centre of the lens. In children, the frames may haev to be changed from time to time, on account of the growth of the head and face. (9) Patients should be personally instructed by the oculist to observe any decentring of their own lenses, that often occurs from bending of the frames or nose-clips; also personally to test the vision of each eye separately from time to time (by means of a test card) to see if the refractive correction remains perfect. (10) Patients should also be cautioned by oculists always to have their lenses verified whenever they fall out of the frames and are replaced, or whenever a lens gets broken and a new one is made. (11) All tests made to determine either the power of individual muscles of the orbit or the presence or absence of equilibrium of the ocular muscles are of no positive value until all errors of refraction are determined and properly corrected by lenses. (12) The first "muscular tests" made upon any patient by the oculist should be recorded as revealing only the "manifest" muscular errors (in contradistinction to "latent" muscular errors); and these tests should invariably be made with the proper lenses placed before the eyes of the patient to correct refractive errors, if any exist. (13) The "manifest" muscular errors (revealed at the first examination) should never be regarded as possessing much clinical importance, except as possible pointers toward some special type of heterophoria and a guide to the oculist in searching for "latent" heterophoria. (14) The most positive and uniform standard of power in any of the ocular muscles (when studying some puzzling case of suspected heterophoria) is the normal power of abduction. (15) A marked difference in the power of sursumduction on the two eyes is always to be regarded as a suspicious sign of hyperphoria. (16) It is usually wise to follow up suspected latent hyperphoria with vertical prisms, prior to any investigation of apparent anomalies of the internal or external muscles, whenever hypoesophoria or hypoexophoria seem to exist. (17) Whenever the refraction of a patient requires the constant wearing of glasses to correct it, the investigation of heterophoria by the wearing of prisms is most easily made through the aid of lorgnette frames that can be attached to spectacle frames by means of small hooks. (18) Operative procedures upon the eye muscles should never be too hastily performed. It is vitally important, to insure the best results in any case, that the effects of accurate refractive correction (and possibly of prisms also) be noted for a time; and that repeated muscular tests be made in any case of heterophoria before any surgical steps for its radical correction be advised or undertaken.

The Use of the Suprarenal Capsule in Diseases of the Heart; a Preliminary Report.—S. Floersheim has noticed no effect upon the normal heart, but found that in cases of mitral regurgitation by giving dry powdered suprarenal gland, gr. v. in a capsule, to be chewed, within from one minute to ten minutes the action of the drug became apparent. In one case he noted that the effects became apparent as rapidly as in fifteen seconds. The pulse grew fuller, stronger, and more regular, the contractions of the heart more rhythmical; the murmur, which was diffused and blurred, became circumscribed, and in two cases the murmur, which was slight, actually disappeared and remained absent for more than fifteen minutes, while in a number of other cases the murmur became reduced in volume, the heart sounds clearer, the murmurs more distinct, more easily recognized and differentiated. In a general way it may be said that under this remedy the rapidity of the heart is not noticeably altered while the tone is improved, especially in conditions of dilatation, and a much better force is induced. Concerning the rapidity of effect he found that manifest effect was apparent at times in ten seconds, while at other times ten minutes were necessary to show any evident change. He uses the extract as an adjuvant to other remedies. No claim is made that it takes the place of nitroglycerin, strychnine, or digitalis.

Implantation of an Artificial Vitreous; "Mules' Operation."—M. L. Foster refers to three cases, two of which were operated on by himself. He finds that the great advantage of Mules' operation is that the glass ball within the sclera maintains the muscular apparatus of the eye in nearly its normal position, and so secures its better action, which results in better motility of an artificial eye when properly fitted. The most serious objection he finds to be the prolonged convalescence, which lasts from ten to fifteen days, about double the length of that following enucleation. Failure of the operation, with extrusion of the glass ball, occasionally happens. It may be the result of the insertion of too large a glass ball, suppuration, or the absorption of catgut sutures in the sclera before the cut edges of that tissue have become firmly united. It seems better to use the smallest-sized ball in every case, and to use silk to unite the edges of sclera. Suppuration is to be guarded against by the observation of strictest asepsis.

Journal of the American Medical Ass'n, Oct. 6, 1900.

The Reefing Operation for Movable Kidney.—Edward Wyllys Andrews describes the technique of this operation as follows: (1) Incision at the outer borders of the quadratus from the twelfth rib to the ilium. This is carried through the lumbar fascia and along the edge of the quadratus to the loose fat about the kidney. (2) The muscles are retracted and the fatty capsule is split the whole length of the kidney. The two flaps thus formed are pulled outside, and the kidney is thus held well up and back. Care should be taken that the lower pouch of this capsule is pulled high up. In cases of great prolapse, the fatty capsule will be found drawn into a long tube, like a stocking. It will surprise one who has not tried it to see how nicely it can be reefed by drawing it out of the skin opening, and how well the kidney obeys every pull we make in the upward and backward direction. It is expected that Gerota's capsule is included. Five or six inches of this fatty sac can sometimes be drawn up. The kidney will now be seen to lie snugly in the lumbar wound, and yet to rise and fall in respiration. Probably it will be an inch or more below its normal place. This is an advantage, because it removes from it the pressure of the liver, and enables us to hold the entire organ and not merely its lower pole. He has had cases of relapse by older methods in which the lower pole was still anchored by his stitches, while the upper end tilted forward and could be felt below the costal arch in front. (3) The broad segments of the fatty capsule, and its enclosing, or Gerota's, fascia already drawn outside are now held by the hands of an assistant or by long forceps, while the opening in the muscular wall is closed by a line of mattress stitches. These transfix the fatty capsule. The real support is obtained, however, not by the stitches, which would cut out, but by compression between the muscles. (4) The flaps should now be cut off an inch or two outside the muscle, everted and stitched down, after which the skin can be closed in any simple manner.

Yellow Fever; its Nature and Cause.—Eugene Wasdin in discussing this subject says that yellow fever has presented a uniform complex of symptoms which distinguishes it clinically from other infections. In a characteristic case, the temperature rises to its maximum within the first twenty-four to thirty-six hours, the pulse rising at first in proportion to the temperature, but this does not continue. Upon the second or third day the temperature generally declines, the patient entering a period of comparative calm. Then comes the third stage with rising temperature. This phenomenon presenting the two accessions of temperature with a decline, the period of calm separating them, has been recognized by southern clinicians as the most characteristic of all the symptoms of yellow fever. Among the clinical phenomena is the "black vomit." Cases of the fever have been divided into three classes—the ephemeral, the grave, and the siderante or fulminantly fatal cases. The writer believes that the bacillus icteroides is constantly present in yellow fever, and that it is the cause of the disease.

Lessons from a First Series of One Hundred Cataract Operations.—F. T. Rogers from a study of these cases draws the following conclusions: (1) More attention should be paid to the general condition of the patient, and the presence of any systemic disturbance should influence the prognosis. (2) All operative procedures on the crystalline body should be done under the best possible illumination. (3) Providing that it is large enough, the exact site of the corneal section does not materially influence the result. (4) The combined operation is the safest and the easiest for the operator of limited experience. (5) The most frequent complications, iritis and iridocyclitis, should be combated by the early instillation of atropine, and their existence does not necessarily prevent an ultimate good result. (6) Discission of the capsule can be done with

comparative safety and materially increases the acuity of vision. (7) Infection of the wound does not in all cases destroy the sight. (8) The patient should be frankly informed of the possible outcome.

The Etiology of Gall Stones.—Frederick C. Shattuck says that little is known of this subject. What we do know is that (1) gall stones are composed mainly of cholesterin, often partly of biliverdin calcium precipitated by changed reaction of the bile. A nucleus may be formed of biliverdin calcium, bacteria, a foreign body, or a combination of these. (2) Gall stones, while not unknown in childhood, are rare under the age of thirty years; from thirty to sixty they are more common, little difference existing between the several decades of this period in point of frequency; after sixty they are more common than in earlier life. (3) They are from two to four times more common in women than in men. Stasis of the bile is a very important etiological factor, and the chief causes of this seem to be, in the writer's opinion, tight lacing and want of exercise, and typhoid fever. He thinks we can get rid of the latter cause more easily than of the former.

The Lancet, September 29, 1900.

A Lymphatic Anæmia Met with in Children.—A. Macgregor has seen within the last few months some twenty-three cases of an anæmia which he does not find described in any of the books. Boys are far more often affected than girls, and the favorite age seems to be between three and eleven years. The cervical triangles become packed with small, hard glands, and there is a chain of them along Poupart's ligament. The spleen is generally enlarged. It is not the condition in which the glands become tuberculous, nor is it gland fever. The axillary glands are never affected, while the bronchial glands frequently are. Catarrhal pneumonia is not uncommon. The anæmia is not always very marked. Examination of the blood shows a decrease of the red and a large increase of the white corpuscles, and of the latter the increase of the large uninucleated corpuscles is very striking. Normally, it is said, lymphocytes form fifteen to twenty per cent. of the white corpuscles, the large uninucleated from six to eight per cent., the multinucleated from seventy to eighty per cent., and the eosinophilic from two to four or seven per cent. Macgregor stained a large number of films of the blood of children suffering from this lymphatic anæmia, and on counting the leucocytes found that the lymphocytes formed from twelve to thirteen per cent., the large uninucleated from twenty to thirty-nine per cent., the multinucleated from forty-one to sixty-three per cent., and the eosinophilic from two to nearly seven per cent. The increase of the large uninucleated corpuscles from six to thirty-nine per cent. is certainly noteworthy.

The Etiology of Rheumatic Fever.—F. J. Poynton and A. Paine have found in this disease a diplococcus concerning which they make the following claims: "(1) We have demonstrated these diplococci in eight successive cases of acute rheumatism. (2) They have been present in five cases in pure culture. (3) We have obtained them (*a*) from the blood of living patients suffering from acute rheumatic pericarditis; (*b*) from the pericardial fluid and from the fragments of granulations removed from the valves after death; and (*c*) from the throat of the living patient suffering from rheumatic tonsillitis. (4) We have isolated them and grown them in an acid medium and also upon blood agar. (5) They have also grown in the pericardial fluid, which we proved on those occasions to be acid. (6) They do not thrive on ordinary media. (7) We have isolated them in pure culture from the joint exudation, heart blood, urine from the bladder, and cerebro-spinal fluid of rabbits that have been inoculated with a sufficient dosage." The authors believe the organism to be identical with those described by Triboulet and Wassermann a few years ago. The rest of the article is devoted to the details of the facts laid down in the general summary given above.

A Case of Rupture of the Anterior Annular Ligament of the Ankle Joint.—The patient of G. W. Ord was a strong boy, aged thirteen years, who had twisted his ankle at cricket. There was slight puffiness just internal to the external malleolus and no ecchymosis, but there was great pain on flexing the foot and on pressure over the swelling. When he stood up with feet uncovered, the big toe could be extended fairly well but not so well as its fellow on the sound limb; the second, third, and fourth toes could not be raised from the ground, though he was just able to communicate movement to them; while the little toe was immobile. Ord applied the battery to exclude the possibility of ruptured tendon, and obtained muscular contraction of the extensor longus digitorum, but with diminished extension, especially of the little toe. Treatment consisted in firm strapping and bandaging. Complete recovery resulted.

The Treatment of Typhoid Fever.—James Barr states that in those cases often protracted by recrudescences and relapses, in which we get evening rises of temperature lasting for one or two weeks and due to secondary infection, we may cut the pyrexia short by a few injections of antistreptococcus serum. The article in general follows along familiar lines.

British Medical Journal, September 29, 1900.

The Significance and Pathology of the Argyll-Robertson Pupil (Illustrated).—Wilfred Harris declares that the loss of the pupil reaction to light is a physical sign of the greatest value in the examination of cases of nervous disease. Of these it is by far the most commonly met with in two diseases, locomotor ataxy and general paralysis, inasmuch as these diseases are due largely if not entirely to previous syphilis, acquired or, in a few cases, congenital. The morbid anatomy of the Argyll-Robertson pupil has never been demonstrated, though it has been variously surmised to depend on a nuclear lesion, or on sclerosis of Meynert's fibres between the anterior corpora quadrigemina and the third nucleus, or even on a lesion of the ciliary ganglion. It is highly probable that in man and other animals with binocular vision, in whom there is semidecussation of the optic nerves at the chiasma, a similar arrangement holds good between the anterior corpora quadrigemina and the third nuclei, namely, that there is a semidecussation of the fibres subserving the light reflex between these two parts. Meynert's fibres have been shown by Boyce and others to be not a complete decussation, some fibres remaining uncrossed in or close to the posterior longitudinal bundle of the same side, and it seems not improbable that these fibres have the above function. This being the case, it is no longer necessary to conceive the two third nuclei being tied together in order to explain the consensual reaction of the pupils to light, as light thrown on either pupil in any direction will thus cause afferent stimuli to reach both third nuclei independently. It seems much more probable then, in the absence of direct pathological evidence, that the Argyll-Robertson pupil is due to sclerosis of these fibres on one or both sides according as the loss of light reaction is unilateral or bilateral, rather than due to any nuclear degeneration such as has been suggested.

The Etiology of Tropical Dysentery.—Simon Flexner believes that the present knowledge of the cause of dysentery may be summed up as follows: (1) No bacterial species yet described as the cause of dysentery has an especial claim to be regarded as the chief micro-organism concerned with the disease. (2) It is improbable that any bacterial species that is constantly and normally present in the in-

testine or in the environs of man, except where the disease prevails in an endemic form, can be regarded as a probable cause of epidemic dysentery. (3) The relations of sporadic to epidemic dysentery are so remote that it is improbable that the two diseases are produced by the same organic cause. (4) The pathogenic action of the amœba coli in many cases of tropical and in certain examples of sporadic dysentery has not been disproved by the discovery of amœbæ in the normal intestine and in diseases other than dysentery. While amœbæ are commonly present and are concerned in the production of the lesions of subacute and chronic dysentery, they have not thus far been shown to be equally connected with the acute dysenteries even in the tropics. In the former varieties bacterial association probably has much influence upon the pathogenic powers of the amœbæ.

Subcutaneous Saline Infusions in Pneumonia.—William Ewart and Beaumont Percival conclude that: (1) In the severe cases treated, no unfavorable results were observed from the saline infusions; (2) these seemed to delay rather than to accelerate the fatal termination; (3) they were not resented by the patients, and by some of them they were acknowledged to be comforting; (4) they were powerless to check the fatal course of the pneumonia in the worst type of cases; (5) they do not seem, except in one case in which no pus but clear serum exuded from the cut surface of the gray hepatization, to have made any difference in the characteristic appearances of the pulmonary changes. At the same time, while results have been disappointing, they do not prove the infusions to be useless. A different composition, a larger bulk, or a greater frequency of administration might lead to very different results. The cases reported were exceptionally severe, and may have been incapable of recovery. But the effects were such as to recommend the method for more extensive trial in cases with anxious prognosis, for there may be among them cases not of the worst type which might be saved by this treatment.

Headaches and Other Nervous Symptoms in Relation to Post-Nasal Adenoids.—David McKeown believes that the condition of the tissues in the nasopharynx and the nasal fossæ, with the consequent obstruction to the vascular and lymphatic circulation and pressure upon nerves, to be an important factor in the production of headache and the allied symptoms, for one of the immediate results of operation is the cure or relief of headache; after many operations without an anæsthetic, patients who had headache at the beginning were free from it a few minutes after completion of the manipulation; even when cerebral symptoms have not been realized, there is experienced a great relief after operation; the anatomical relations of the pathological area with the intracranial contents are very intimate; headache is a symptom of acute nasal catarrh and also of evanescent attacks of nasal congestion as well as a feeling of weight or oppression in the region of the forehead, an inability or disinclination for mental or physical work, and a general depression of the vital functions. These concomitants of headache are found in cases of adenoids.

On Intermittent Pulse (with Diagrams).—Arthur R. Cushny believes that intermissions of the pulse may be divided into several classes: (1) True ventricular intermissions in which the pause is exactly equal to two pulse intervals, and during which there is no cardiac sound; (2) true auricular intermissions in which the pause is shorter than two pulse intervals, and during which there is no cardiac sound; (3) false ventricular intermissions, in which the pause is equal to two pulse intervals, but is often interrupted by a slight elevation; (4) false auricular intermissions, in which the pause is shorter than two pulse intervals; (5) another form which has been described by Wenckebach. The treatment of cardiac disease may be rendered more exact by the careful examination of the pulse, which may indicate whether the existing condition is that of excessive irritability or of deficient activity.

Two Cases of Lipoma of the Kidney.—W. S. Lazarus-Barlow says that lipoma is apparently a very rare condition, judging from the statements concerning it in books. In both these cases which he reports, the tumors were removed under the impression that they were small secondary deposits. In the one case, the prime lesion was a glioma of the brain; in the other, an intense suppurative meningitis arising from disease of the antrum. Both the patients were adults—a man aged seventy years, and a woman aged thirty years. The growths were approximately spheroidal, about the size of a Spanish nut, and found in the cortex just beneath the capsule, to which they were not adherent. Lipomata of this size are only pathological curiosities, but occasionally one is met so large that it is the object of operative interference.

The Origin of Gout.—William Ringrose Gore presents the following conclusions: (1) Gout is not due to the presence of uric acid in the blood. (2) The symptoms of gout are due to a toxin. (3) The concurrent presence of uric acid is due to the action of the toxin on the liver. (4) The toxin is formed by the action of one of the intestinal bacilli on an intestinal secretion specifically altered by diet, this alteration being assisted by hereditary disposition.

A Discussion on the Pathological Distribution of the Diphtheria Bacillus and the Bacteriological Diagnosis of Diphtheria.—By F. W. Andrewes and others.

General Actinomycosis with Localization in the Brain.—Nikitin's case began with pharyngitis and an obstinate dry cough, while later on signs pointing to a slight tuberculous infiltration developed at the left apex. No tubercle bacilli were found in the sputum, however, and some time later an abscess developed below the left clavicle. This was opened, but was succeeded by another in which the ray fungus was found. Potassium iodide was given in large doses, but this did not prevent the formation of further metastases about the thorax, fingers, tibia, and femur. Finally severe cerebral symptoms (convulsions, headache, paralysis, aphasia) set in, and the patient passed into the comatose state and died. On section a walnut-sized actinomycotic abscess was found just posterior to the left frontal convolutions.

Prolapse of the Fœtal Intestines during Labor.—Jaerisch was called to deliver what apparently was a lateral presentation. On digital examination the fœtal small intestines were found filling the vagina, and the hand could be passed into the child's abdominal cavity through a defect in its anterior wall. Version was impracticable, and embryotomy had to be done before delivery was possible. The fœtus was then found to be a monster with imperfect frontal development, a large left-sided encephalocele, hare lip, deformed thorax, right arm atrophied, syndactylism of the right toes, and a five-inch cleft in the abdominal paries permitting the escape of intestine and liver.

The Theory of Infection.—Hugo Marx proposes the following theory: A bacterium effects its passage from the non-infectious or virulent to the infectious or virulent state through the intracellular condensation and localization which results in the formation of the Babes-Ernst bodies. The index for present virulence is to be found in the number of individuals containing these bodies, for future virulence in the ability of the cells to produce them.

Acute Leukæmia.—A. Dennig believes that many cases diagnosed as scurvy or Werlhof's disease would, if a blood examination were made, turn out to be acute leukæmias. In illustration he details an instance in which the history, symptoms, and physical signs seemed to justify the diagnosis of sporadic scurvy until on examination the blood was found to be that of leukæmia, showing the importance in all cases of stomatitis of unknown origin, especially if accompanied by the hemorrhagic diathesis, of making a hæmatological investigation. Acute leukæmia is not to be differentiated from the chronic form by any stated time measure, but whenever the disease from the

outset presents symptoms and lesions usually not observed until late, it may be considered acute. In addition to the usual symptoms of progressive asthenia, palpitation, syncope, pallor, hemorrhagic petechiæ in the skin, mucous membranes and internal organs, swelling of the liver and spleen, etc., which are common also to the chronic form, there is a marked difference in the character of the blood changes which serves to distinguish the two. In acute leukæmia there is an increase of the uninuclear elements exclusively; these belong to the class of lymphocytes and are present in all sizes. They possess a large round nucleus surrounded by a narrow rim of poorly staining nongranulated protoplasm. Multinuclear leucocytes and normoblasts are scanty, while the uninuclear cells with neutrophile granules and the eosinophile myelocytes typical of the chronic form are entirely absent.

The Occurrence and Diagnosis of Gout.—Strümpell comments on the increasing frequency with which the diagnosis of gout is being made, and thinks it is due to a better recognition of its nature rather than to any greater prevalence of the disease. Characteristics which distinguish it from acute articular rheumatism are the tendency to attack the joints of the lower extremity, especially those most distal, like the metatarso-phalangeal articulation of the great toe, the fact that only one or but few joints are involved, the frequency of the attacks, and their short duration. Masked gout is often confounded with arthritis deformans, but a careful study of the history usually makes the distinction clear. Various painful affections of the foot, tarsalgia, achillodynia, atypical ischialgia are often of gouty origin. Of the internal changes the gouty kidney takes first place; the organic lesion is usually recognized, but the causative factor is overlooked. Concerning the degenerative changes in the heart and arteries which so often accompany gout, it is hard to say to what degree they are the result of the specific poison of the disease and how large a part in their etiology is played by the usually concomitant alcoholism and luxurious habits of living. Of the etiology of the disease in general, it may be said that while such poisons as alcohol and lead seem to be directly responsible for the trouble in the majority of cases, still the element of heredity is the governing factor and is present in nearly all instances.

Malignant Œdema.—G. Muscatello and C. Gangitano draw the following conclusions from the clinical observation of five cases of the disease and a bacteriological study of the morbid tissues. Two micro-organisms, the bacillus aerogenes capsulatus and the bacillus coli communis, stand in direct causal relationship to the affection. Of these the former is to be regarded not as the specific producer of the disease, but as a gas-forming organism which is simply a toxic saprophyte and is able to locate itself only where the vitality of the tissue has become depreciated to a serious degree. The bacillus coli communis is usually associated with other organisms and is capable of producing malignant œdema. Clinically two courses of the disease are to be noted. The first of these, due to the bacillus aerogenes capsulatus alone, is unaccompanied by inflammatory manifestations, does not exhibit a very marked tendency to spread, and assumes a rapidly progressive course only in the later stages when the organism has become incapable of further resistance. The other form, resulting from a mixed infection, is usually inflammatory in nature and rapidly invades surrounding parts from the very beginning. Although malignant œdema is one of the most serious of infections, the prognosis is no longer as grave as was formerly supposed. Through free exposure of the focus, early and complete extirpation of the entire necrotic mass, and energetic disinfection, a favorable result may be looked for in a large number of cases.

Berliner klinische Wochenschrift, Sept. 10, 1900.

Gonorrhœal Joint Inflammation.—F. Rubinstein distinguishes four forms of this affection: (1) Gonorrhœal hydrops; (2) fibrino-serous exudation; (3) purulent inflammation, empyema of the joint; (4) phlegmonous inflammation. To relieve the first he advises rest of the joint, iodine applications, blisters or vasogens (guaiacol or creosote). If the amount of fluid is great, puncture. Some writers inject a five-per-cent. carbolic solution. For the fibrinous form Rubinstein advises rest, immobilization, and elevation of the joint with splints and plaster bandages, an ice-bag being applied if pain is severe. Purulent accumulations call for incision and drainage. Later, when all active manifestations have come to an end, massage and warm baths are to be recommended.

Local Trophic Effect of Gentle Abdominal Massage.—Saquet speaks of the effect of gentle abdominal massage, citing two cases. The first was that of a young man aged twenty years, who for six months had been suffering with his stomach. In spite of varied treatment he was gradually growing worse and looked like one in the last stages of phthisis. He suffered from constipation and insomnia; he was very nervous, and was convinced that he was about to die. After instituting the abdominal massage, his condition rapidly improved; his abdomen, which had resembled that of a child with meningitis, became supple and daily enlarged. The treatment was not severe nor very special. His pain disappeared, and he was able to digest all that was given to him. The patient gained in six months about sixty-five pounds, which he has not lost since that time, now five years ago. The second case was that of a woman aged fifty years, who had been sickly since birth. She presented all the symptoms of enteroptosis of the last degree. At the end of a few weeks the patient returned in a condition of health which she had not known for years. The author believes that by diet alone it will often take years to obtain improvement, while with massage added the benefit will be noted in a few weeks.—*La Médecine Moderne*, September 19, 1900.

Treatment of Genital Prolapse in the Woman.—Coville divides prolapse into three sections: (1) Partial prolapse; (2) complicated prolapse (tumors, hypertrophies, or uterine deviations); (3) complete prolapse. Prophylaxis should consist in keeping the parturient woman in bed from ten to twelve days at the least. Any laceration should be immediately repaired. Curative treatment should consist in operating for prolapse, whatever the degree, unless there exists the contraindication of an inoperable malignant tumor. The time of pessaries has passed and ought now to give way to surgical treatment, rational and benign, and which promises to the patient not only relief from suffering but the integrity of her functions.—*La Presse Médicale*, September 19, 1900.

The Treatment of Biliary Lithiasis.—A. Gilbert and L. Fournier state that certain hygienic rules by themselves constitute true prophylactic measures against lithiasis—regular meals, the use of clothing producing neither displacements nor deformity of the abdominal organs, exercises, care about the digestive functions—one of the principal results being the avoidance in a certain measure of biliary stasis and ascending infection. To these measures may be added the use of alkalies, cholagogues, abdominal massage, and cold intestinal injections. This same treatment is indicated after the establishment of lithiasis. When serious complications are threatened, then surgical intervention is indicated.—*Journal des Praticiens*, September 22, 1900.

Epididymo-Testicular Tuberculosis Treated by Ligatures of the Spermatic Cord.—P. Mauclaire, in describing this operation states that he generally ties and cuts *en masse* all the spermatic cord. The cord is tied very high, near the external orifice of the inguinal canal. Two ligatures are used, about 2 cm. apart. Sometimes chloroform is used, sometimes only cocaine. Sometimes he has curetted the focus, sometimes incised it. At times he has used the thermocautery. His results have been most encouraging. Instead of castration, there is a chance of saving the testicle even if it atrophies a little, while the method is not dangerous.—*La Presse Médicale*, September 22, 1900.

The Journal of Experimental Medicine, October 1, 1900.

An Experimental Study of Oxaluria, with Special Reference to its Fermentative Origin.—Helen Baldwin concludes her discussion of this subject as follows: (1) As varying amounts of calcium oxalate may be held in solution in the urine, conclusions based upon the presence or number of calcium-oxalate crystals found therein are of no real value as an indication of the quantity of oxalic acid present. (2) Unless the utmost care is exercised, the results obtained by quantitative estimation of oxalic acid are subject to large percentages of error. This is especially true in the use of Neubauer's or Schultzen's methods, in which the calcium oxalate is precipitated in an alkaline solution. (3) An ordinary mixed diet regularly contains traces of oxalic acid or its salts. (4) A portion of the oxalic acid ingested with the food may be absorbed and reappear unchanged in the urine. (5) The normal daily excretion of oxalic acid in the urine fluctuates with the amount taken

in the food, and varies from a few milligrams to 2 or 3 cgm., being usually below 10 mgm. (6) In health, no oxalic acid, or only a trace, is formed in the body, but that present in the urine has been ingested with the food. (7) In certain clinical disturbances which in some of the cases studied above were associated with absence of free hydrochloric acid from the gastric juice, oxalic acid is formed in the organism. (8) This formation in the organism is connected with fermentative activity in the alimentary canal. (*a*) The prolonged feeding of dogs with excessive quantities of glucose, together with meat, leads eventually to a state of oxaluria. (*b*) This experimental oxaluria is associated with a mucous gastritis, and with absence of free hydrochloric acid in the gastric contents. (*c*) The oxaluria and the accompanying gastritis are referable to fermentation induced by the excessive feeding with sugar. (*d*) The experimental gastritis from fermentation is associated with the formation of oxalic acid in the gastric contents. (9) The symptoms attributed to an oxalic-acid diathesis, with the exception of those due to local irritation in the genito-urinary tract, do not appear to be due to the presence in the system of soluble oxalates, but are more likely to depend on other products of fermentation and putrefaction.

Proliferation and Phagocytosis.—F. B. Mallory declares that the effects which injurious agents, especially the toxins secreted by bacteria, produce on tissues are manifested in four different ways: (1) By degeneration or necrosis of cells; (2) by exudation from the blood-vessels; (3) by proliferation of cells; (4) by phagocytosis, this term being used here to mean the inclusion and digestion of certain cells by other cells. These four processes may occur separately, or in various combinations and proportions. The author's object in this paper is to show that strong toxins cause degeneration or necrosis of cells and exudation, while dilute and weak toxins produce proliferation and phagocytosis. The results of the study of large numbers of cases of certain diseases and of typical and unusual lesions support this hypothesis. The statement of the proliferation and phagocytosis occurring in diphtheria is based on the histological study of two hundred and twenty cases. Pratt has recently shown in a study of fifty cases of acute lobar pneumonia that micrococcus lanceolatus causes marked proliferation of the cells lining the alveoli, the pleural cavities, and the lymphatics; these newly formed cells are very phagocytic. The acute lesions of the glomeruli of the kidney throw much light on the question of proliferation due to bacterial toxins. The typhoid and tubercle bacilli produce mild toxins which act slowly and usually produce proliferation only. The kind of cells which a phagocyte incorporates depends on its situation in the tissue. In acute proliferative intracapillary glomerulo-nephritis the writer has never found any evidence of phagocytosis. The tendency of the cells which proliferate under the action of toxins is to degenerate and disappear as soon as the agent to which they owe their existence is destroyed or neutralized. The processes of proliferation and phagocytosis which have been described as due directly to the action of toxins are regarded generally as reparative in nature. Similar processes occur in repair. The phagocytic cells are phagocytic beyond all bounds of necessity and destroy great numbers of active, useful cells. These are all abnormal and to a certain degree malignant properties.

Pathological Report on a Case of Dermatitis Vesiculo-Bullosa et Gangrænosa Mutilans Manuum (Duhring), with a Consideration of the Relations of Vascular and Nervous Changes to Spontaneous Gangrene and Raynaud's Disease.—William G. Spiller draws the following conclusions from the study of this case: (1) Gangrene may be caused by endarteritis obliterans. (2) Alteration of nerves alone without alteration of the vessels is believed by some to be a cause of gangrene. We need probably more evidence before this conclusion can be definitely accepted. (3) Gangrene may cause degeneration of the vessels, especially of the portions near the gangrenous area. (4) Gangrene is less liable to cause degeneration of nerves except of the portions within or near the gangrenous areas. (5) Sudden closure of blood-vessels causes degeneration of the nerves nourished by these vessels, unless an adequate collateral circulation is promptly established. If the vascular disease is of a chronic type the nerves may escape, at least for a time, but do not always do so, the result doubtless depending upon circulatory conditions which vary in different cases. (6) Degeneration of nerves is a possible, but not thoroughly demonstrated, cause of degeneration of the blood-vessels.

Refractory Subcutaneous Abscesses Caused by Sporothrix Schenckii. A New Pathogenic Fungus.—Ludvig Hektoen and C. F. Perkins describe an organism which is undoubtedly identical with that described by Schenck in the bulletin of the Johns Hopkins Hospital for December, 1898. To study an abscess of this nature, it should be excised in an early stage of formation. It is very interesting to note that we have here a pathogenic fungus that in the lesions it produces in animals exists in the spore-form, or in a modified spore-form, and that it undoubtedly multiplies as such; threads do not seem to develop in the tissues of susceptible animals. This fungus produces a slow, circumscribed, and nodular inflammation with necrosis and pus formation in the centre, and the development of granulation and fibrous tissue at the periphery—encapsulation. A characteristic clinical feature of the human cases is the refractory nature of the subcutaneous abscesses. In the three cases on record there appeared a succession of these abscesses on the upper extremity consequent upon injury: the scratch of the skin of the finger by a nail; the blow upon the finger by a hammer; the puncture of a finger by a wire.

A Study of the Neurofibrils in the Ganglion Cells of the Cerebral Cortex.—By Stewart Paton.

Annals of Surgery, October, 1900.

The Surgical Treatment of Primary Renal Tuberculosis, with a Consideration of the Immediate and Remote Results after Operation.—The conclusions drawn by Otto G. Ramsay are summarized as follows: (1) That renal tuberculosis may be classed as a semi-malignant form of inflammation, and that for this reason surgical treatment of some sort is always indicated; (2) that this surgical treatment will have a palliative or a curative end in view depending on the condition of the patient and the duration and extent of the disease; (3) that nephrotomy in renal tuberculosis is to be classed as a palliative operation; and that as a palliative operation for the immediate relief of dangerous symptoms, and as not precluding a later nephrectomy, nephrotomy with drainage of the abscess cavity is most valuable; (4) that resection of the diseased part of the kidney is contraindicated in renal tuberculosis because of the danger of leaving a tuberculous focus in the portion left in the body; (5) that nephrectomy or nephro-ureterectomy is indicated in every suitable case, and in suitable cases should be followed by a lasting cure in 55.5 per cent. of the cases; (6) that the indications against nephrectomy are tuberculous or other disease of the second kidney, or tuberculous foci in other organs; (7) that tuberculosis of the bladder is not to be considered a contraindication to nephrectomy, as it will probably heal later; (8) that a small tuberculous focus in the lung, if the patient otherwise is in good condition, may sometimes not be considered a contraindication; (9) that in doubtful cases, when it is questionable whether the patient can stand an immediate nephrectomy, it is better to do a nephrotomy, following it later by nephrectomy; (10) that the clamp method of controlling the pedicle is contraindicated from the danger of hemorrhage after the removal of the clamp; (11) that it is safest to remove the ureter with the kidney, as a persistent fistula may give trouble if it be allowed to remain in the body; (12) that a certain proportion of these fistulæ will finally disappear, either after the removal of a deep suture, or because of the slow disappearance of the tuberculous disease in the ureter, which in these cases gradually changes into a fibrous cord; (13) that we may expect a steadily increasing number of final cures as our means of diagnosis improve, and as our surgical technique is carried out more carefully and scientifically.

Mesenteric Cysts.—By C. N. Dowd. The patient was a woman aged forty-one years. The cyst was remarkable in the following particulars: (1) It showed the exact structures and fluid contents of an ovarian cyst-adenoma, and hence suggested its probable origin from an embryonic ovarian sequestration. (2) It showed in the smaller loculi the epithelial structure which explained its growth, and in the main cyst wall the firm fibrous structure which has been found in most mesenteric cysts. (3) It contained clear fluid in some of its loculi and bloody fluid in others, and showed large blood-vessels in the delicate cyst walls, thus indicating that hemorrhages from the cyst walls explained the sanguineous fluid, and suggesting a similar cause in other sanguineous cysts. A general consideration of mesenteric cysts is summarized as follows: (1) The occurrence in the transverse mesocolon of a multilocular cyst-adenoma which contained pseudomucin, and which was exactly like a cyst-adenoma of the ovary, suggests its probable origin as an embryonic ovarian sequestration. (2) The occurrence of dermoid cysts in a similar position suggests a similar origin. (3) The occurrence of chylous cysts in the mesentery, which have the structure and ap-

pearance of ovarian and parovarian cysts, and which have in their walls lymph vessels, suggest embryonic cysts into which there has been an effusion of chyle. (4) The sanguineous cysts appear to be preformed cysts into which hemorrhage has taken place; hæmatomata in the mesentery should not be described as cysts. (5) The presence of cysts which have the structure of the intestinal wall suggest sequestration from the intestine. (6) Serous cysts are apparently similar in origin and structure to the cysts already considered. They are usually not situated in the path of the lacteal vessels. (7) Hydatid cysts form a class by themselves and are due to the tænia echinococcus. (8) Reports indicate that mesenteric cysts are being removed at least as often as once a month. If microscopical examinations of the cyst walls and chemical and microscopical examinations of the cyst fluid are made, the entire subject should soon be understood. (9) It is probable that all mesenteric cysts may be included in the classifications (*a*) embryonic cysts, (*b*) hydatid cysts, (*c*) cystic malignant disease.

Tetanus: a Study of the Nature, Excitant, Lesions, Symptomatology, and Treatment of the Disease, with a Critical Summary of the Results of Serum Therapy.—A. V. Moschcowitz concludes a very lengthy article by calling attention to the following points: (1) All forms of tetanus are caused by the bacillus of Nicolaier; hence the diagnosis of rheumatic or idiopathic should have no room in our nosology. (2) The tetanus toxins appear to have a decided affinity for the anterior horns of the spinal cord, which may be distinctly recognized by Nissl's method of staining. (3) The cerebrospinal fluid of tetanus patients is more toxic than the blood. (4) The antitoxin therapy appears to have a distinct beneficial influence upon the course of tetanus. (5) With the antitoxin treatment the mortality percentage has been reduced from about ninety per cent. to forty per cent. (6) Although the use of the serum is a most important factor in the treatment of tetanus, the other recognized therapeutic measures should not be neglected.

The Treatment of Pulmonary Tuberculosis and Diseases of the Respiratory Passages with Organo-Toxin.—De Lannoise applies this name to an attenuated toxin obtained by keeping bouillon cultures of tubercle bacilli at a temperature of 98° to 100° F. for a period of from two to four months. Treated in this way the product is harmless when injected into men or animals, and exercises a very favorable effect on the course of tuberculous disease. After a few injections respiration becomes more free and deep, the cough and expectoration are increased, the expectoration losing its mucopurulent character, becoming first yellowish, then white, and finally disappearing entirely. Cavities already present apparently cicatrize, the temperature drops and stays down, and the digestive and renal functions are greatly improved. The rationale of this action is not entirely clear; apparently it is not the bacillus but the body cell which is acted on and made more resistant to the pathogenic agent.

The Significance of Heredity in Pulmonary Tuberculosis.—F. Reiche, basing his conclusions on statistics obtained by examination of over one thousand cases, believes that the prevalent idea that a family tendency to tuberculosis may exist, and that individuals may from birth be predisposed to this infection, is erroneous. While it is undoubtedly true that oftentimes the offspring of markedly phthisical parents is lacking in stamina and resisting-power, just as is the case in the children of those cachetic from other reasons, *e.g.*, cancer, nephritis, or cirrhosis, yet in the majority of instances the child acquires the disease, which may lie dormant for years, by direct infection from the diseased parent. This is an encouraging view, for it permits the hope that with increasing care in the prophylaxis such infections may be greatly diminished and the dread of a hereditary taint be robbed of much of its terror.

The Marriage of Phthisical Patients.—C. Gerhardt says that on the one hand it has been proposed to make the marriage of tuberculous subjects a legal offence, and on the other it has been stated that the better care, greater comfort, more regular habits, and mental quietude attending the married state more than counterbalance the dangers. He himself is of the opinion that the risks are quite as grave as usually considered, and while exceptionally favorable cases are to be found it is still the physician's duty to warn the public most emphatically of the dangers accompanying such unions. In general it should be demanded of a tuberculous individual that before matrimony he should have been perfectly healthy for at least a year.

The Educational and Legislative Control of Tuberculosis.—Charles Denison ascribes a large part of the morbidity from tuberculosis to deficient ventilation in dwellings. Owing to the rebreathing of devitalized air the lungs grow inactive, and there is gradual clogging of the out-of-the-way air cells with the products of combustion, and a damaging form of local auto-intoxication follows. Legislation should provide for each individual in a living-apartment fifteen hundred cubic feet of air space and a minimum ventilation of two thousand feet per hour per person. Courses in ventilation should be instituted in institutions of learning, and governmental commissions be appointed properly to investigate and study the subject.

Experimental Contributions to the Understanding of Tuberculous Toxæmia.—E. Maragliano, by injecting the blood of tuberculous individuals prepared in various ways and precipitates obtained from their urine into guinea-pigs and rabbits, was able to determine that (1) patients giving clinical evidence of toxæmia had in their blood (injected as such, in the form of a glycerin extract or as blood serum), and also in their urine, substances which when injected into healthy or tuberculous animals produced toxic symptoms; (2) that this intoxication resembled that produced by tuberculin; (3) that this toxic property could be neutralized by a simultaneous injection of tubercle antitoxin.

The Diagnostic Value of Koch's Tuberculin.—Albert Fraenkel says that the reaction against the use of this agent, which was the natural result when it was found that not only was it useless as a therapeutic agent but also that even as a means of diagnosis its employment was not free from danger, has gone too far, and that properly and carefully administered it gives valuable information with very little risk. A large portion of the undesirable by-effects and sequelæ attributed to the reagent are due solely to the unnecessarily large doses which it has been customary to give.

Tuberculous Gastric Ulcer in Connection with a Case Ending Fatally.—Theodor Struppler's case presented the rare picture of a tuberculous ulcer which almost entirely surrounded the pylorus and perforated, inducing a fatal secondary peritonitis. The patient was a youth aged eighteen years, who was also suffering from pulmonary tuberculosis and tuberculous enteritis. The author believes that in this case the infection was due to the swallowing of sputum containing bacilli.

How Does Infection of the Intestine Take Place? (To be concluded).—By Buttersack.

Respiratory Exercises in the Treatment of Pulmonary Tuberculosis.—By Schultzen.

Archives Générales de Médecine, September, 1900.

The Psychology of Phthisis.—Maurice Letulle believes that certain psychical and intellectual changes occur during the course of this disease. In the early stages there is a species of hyperexcitability in the mental state, a feverish desire for occupation, change, and society, followed later by mental lassitude and indolence, a veritable intellectual neurasthenia. As to the moral state of the patients, some retain their strength and beauty of character through their long illness until the end, others undergo a species of psychic irritability. Melancholy is the rule, with an indifference which is plainly shown in the facial expression. Egotism is apt to follow, tuberculosis being of all diseases the one most conducive to the "contemplation of self"—"Myself, always myself, myself alone, whatever happen." All affection and every service are accepted as a right. Jealousy is apt to be marked, rendering the lives of those who care for the patient hard in the extreme. The consumptive is impatient of every little discomfort, and unforgiving of neglect. For the treatment of these sad changes in character no amount of reasoning will have one-hundredth part of the effect that is produced by warm sunshine, the light of warm countries, flowers with their sweet perfume, a view of the sea, and beautiful scenery of all kinds.

The Diabetograph.—Under this name F. Coulon describes an instrument devised for the purpose of rapidly and automatically estimating the amount of sugar contained in the urine of diabetic patients. In consists of a glass cylinder 20 cm. in length, bell-shaped at the mouth, tapering to the other extremity where there is a stop-cock. Figures are marked along the tube. The cylinder is filled with the

urine to be analyzed, and by careful management of the stop-cock allowed to flow drop by drop into a small glass receptacle in which 2 c.c. of Fehling's solution diluted with six times its volume of distilled water has been allowed to come to the boiling-point. When the desired reaction is obtained, the number opposite the level of the urine in the tube will indicate the amount of glucose to the litre of the urine. The diabetograph is based upon the two following principles: (1) All urine which is capable of reducing an equal volume of Fehling's solution contains 5 gm. of sugar to the litre. (2) The amount of urine necessary for the reduction of Fehling's solution is in inverse proportion to the amount of sugar contained.

The Development of Typhoid Fever during the Course of Active Syphilis.—G. Etienne from a study of several cases concludes that syphilis renders more grave the prognosis of typhoid. On the other hand, typhoid may aggravate the condition of the coexistent syphilitic lesions, which may under its influence lead to dangerous complications, such as gangrene of the vulva, which occurred in one of the cases reported. Typhoid fever may perhaps cause a reawakening of syphilitic lesions.

Revue de Médecine, September 10, 1900.

A Case of Compression of the Superior Vena Cava.—Ch. Dopter reports the case of a man apparently in good health, in whom the following symptoms appeared: Gradual increase in size of the neck, with swelling and congestion of the face; œdema of the anterior thoracic wall, and varicosities at the base of the thorax, soon extending upward; upper limbs œdematous and cyanosed. The subjective symptoms were retrocostal and scapular pain, vertigo, attacks of suffocation, dysphagia, dysphonia, but no palpitation. Vesicular murmur was lessened in the right lung; a soft souffle was heard with both inspiration and expiration in the right bronchus; to the right of the sternum were simple beatings, synchronous with those of the heart. The *x*-rays showed an aneurism of the aorta, and the following diagnosis was made: An aneurismal ectasis of the ascending portion of the arch of the aorta and a part of the transverse portion, which by its development had compressed the superior vena cava, the right bronchus, the pneumogastric and left recurrent laryngeal nerves. Syphilis was undoubtedly the cause of the condition, and mixed treatment resulted in a partial cure.

Pneumothorax with a Valve due to Pleural Adhesions.—F. Duplant concludes a study of this form of disease by saying (1) that pleural adhesions do not prevent the production of pneumothorax. (2) The frequent formation of adhesions in tuberculous patients explains the fact that the pneumothorax occurring in the phthisical is at first partial or enclosed within septa. (3) Pneumothorax in tuberculosis with a broncho-pleural fistula usually acts like pneumothorax with a valve. (4) The existence of a membranous valve closing the orifice is altogether exceptional. (5) Treatment is scarcely ever palliative. To be curative it should be directed to the obliteration of the broncho-pleural fistula.

Premature Medullary Syphilis with Brown-Séquard's Complex of Symptoms (Hemiparaplegia with Crossed Hemianæsthesia.—By M. Brousse and Ardin-Delteil.

Hypertrophic Hepatico-Pancreatic Sclerosis with Hypersplenomegaly.—By Georges Guillain.

A Chinaman's First Ambition.—The first ambition of every Chinaman is to have a splendid coffin. A poor man will starve himself for years to buy one. It is always received with great ceremony on its arrival at the house, and is regarded as the most valuable piece of furniture in the establishment. It is kept in the place of honor. There are many strange customs connected with the funeral rites. One of these is the burning at the tomb of paper horses, idols, umbrellas, and clothes. These are supposed to be necessary or useful to the man when he gets to heaven. By being burned they undergo some material resurrection and meet him there.

OUR LONDON LETTER.

(From our Special Correspondent.)

PLAGUE—WAR HOSPITAL COMMISSION—MORE CONTRADICTION TO MR. BURDETT-COUTTS—CRUELTY TO BRITISH PRISONERS—REPORT OF ASYLUMS COMMITTEE—BIRMINGHAM UNIVERSITY—HUXLEY LECTURE.

London, September 24, 1900.

The progress of the plague in Glasgow has not been so reassuring to the public this week as last, but then the public is greatly influenced from day to day by variations in the figures which do not alarm those in charge of the hospitals. On Monday five fresh cases were reported—the total being twenty-two, with one doubtful. One patient has since died, making the fifth death, of which two occurred in the Belvedere Hospital and the others outside. The figures last night were twenty-one cases, one doubtful, and one hundred and five persons isolated as "contacts." One of the new cases was that of a woman who had been employed as a ward-cleaner. She had been inoculated with serum soon after the outbreak, and her attack was extremely mild; Dr. Chalmers, the medical officer of health, thinks that if more serum had been injected she would have been quite immune, but the remedy was available only in small quantity at first. Now there is an abundant supply.

It is quite clear that the disease in Glasgow is in its mildest form. The progress of the cases and the death rate both show this. In India a rate of forty per cent. is common. Here, on the highest computation, it has not exceeded half that. This is better than even Sidney—the lowest rate I call to mind, and which showed one hundred and three deaths out of three hundred and three cases.

The circumstances at Glasgow are far more favorable than they were at Oporto when plague broke out there last year. Every effort has been made to prevent the spread of the disease, and so far with considerable success, for twenty-two cases in a month and only five deaths certainly encourage the belief that the sanitary authorities are waging a successful war. Even in Glasgow, however, there may be found weak joints in her armor, but her authorities are making every effort to find them. We must not, however, forget that there is a danger of other places becoming infected. For a considerable period now the West has been threatened, and with here and there small outbreaks occurring we have frequent warnings that we are not immune to the pestilence.

Professor Muir's report on the cases shows that the bacillus pestis was found and cultures produced the disease in animals.

Glasgow has parliamentary powers permitting the prohibition of holding "wakes" over the bodies of persons dead of infectious diseases. The magistrates have first of all urged upon the Roman Catholic priests to discountenance wakes, as at one of these the outbreak occurred. The priests say watching the dead is a solemn act. No doubt it is. But one would suppose that in times of danger they might assist the authorities. The fact is, these solemn acts too often degenerate into drunken orgies.

Lord Kitchener has given evidence before the hospitals commission which further controverts Mr. Burdett-Coutts. His lordship admitted some delay in the supply of stores, but said this was inevitable owing to the rapid advance. The field hospitals he held had done their work remarkably well. He had frequently ridden with Mr. Coutts, who never once made a complaint to him. Had he done so it would have been immediately investigated. The medical staff worked tremendously hard, and the civilian doctors did excellent service.

Lord Stanley, private secretary to Lord Roberts and principal censor, denied that criticisms on the hospitals were stifled. Mr. Burdett-Coutts was given every facility until Lord Roberts thought he had had time enough to acquaint himself with the facts and should return to Cape Town. When an order was given to that effect, Mr. Coutts said if he could not have more time he would have to make a bad report. This seems very like a threat, and may well be compared to the spite of the society ladies when they were excluded from the hospitals. Mr. Coutts has now been so much contradicted that no reasonable person can place reliance on his statements. I have mentioned only a few of the more important contradictions. They suffice for the present, and we can await calmly the report of the commission for other evidence.

Another inquiry arising out of the war is that into the treatment of British prisoners by the Boers. This has now been published and shows a good deal of cruelty. Lord Roberts says "the inhuman treatment of the sick prisoners throws the greatest discredit on the authorities at Pretoria." He speaks of the efforts of Drs. P. H. Hay-

lett and R. von Gernett to ameliorate the condition of their patients as the gratifying features of the inquiry. On the other hand, he says, it "would be difficult to condemn too strongly the conduct of Dr. H. P. Veale." You will deeply regret that any doctor should have laid himself open to such a verdict from so mild a judge as Lord Roberts.

The report of the asylums committee of the County Council for the year ending March 31st shows a diminution in the number of lunatics from 21,393 in the previous year to 21,069.

The first session of the medical faculty of the new University of Birmingham will be opened on October 1st, when Professor Windle, M.D., D.Sc., will deliver an inaugural address. Dr. Windle is the dean of the medical faculty.

Lord Lister will give the Huxley lecture on October 2d.

WHY GYNÆCOLOGISTS ARE RELUCTANT TO USE ELECTRICITY.

To the Editor of the Medical Record.

Sir: I have read with much amusement Dr. Robert Newman's ingenuous article entitled "Electricity in Gynæcology, and the Present Reluctance of Gynæcologists to Use Electricity," published in the Medical Record for September 29th. I say "amusement" and "ingenuous," because the doctor surely cannot have intended his question seriously, when he asks why gynæcologists have discarded electricity in their practice. Where has my venerable friend spent the last ten years that he needs to ask this naïve question, which—after reciting at some length his own experience of many years, and stating that he "has treated successfully with electricity most of the diseases above enumerated" (his list includes the majority of pelvic diseases in the female, from abrasion of the os uteri to extrauterine pregnancy) and "has always treated his cases of fibroid tumor successfully by electricity"—he finally fails to answer, remaining content with the conclusion that "the reluctance of gynæcologists to apply electricity, or at least to recommend it, has not been explained."

If the doctor had chosen to look outside of the circuit of his batteries, and had followed the progress of gynæcology in the last ten or fifteen years, even ever so slightly, he would have found the explanation for the abandonment of electricity by gynæcologists in the fact that the recent improvements in antisepsis and in surgical technique, and their consequent better acquaintance with many pathological conditions in the female pelvis, have taught them that they can cure the majority of those conditions far more easily, rapidly, and safely by the use of the knife and its allies than by any form of electricity, how, how long, or by whom applied.

I speak as a former believer in "Electricity as a Therapeutic Agent in Gynæcology," having published my experience in a paper with the above title in the *American Journal of Obstetrics* for December, 1885 (an article of forty-one pages, which seems to have escaped Dr. Newman's observation, although it was thought worthy of translation into French by P. Menière, Spanish and Russian), and in a second, "My Recent Experience with Electricity in Gynæcology," *Journal of Obstetrics*, June, 1890; as well as in a chapter on the subject in Thomas and Mundé, 1891; and I reported one case of cure of a tubal pregnancy by the constant current (see Medical Record and *Journal of Obstetrics*, October, 1884) when the patient almost died from shock, but rallied and is still alive. But who would to-day dream of curing a tubal pregnancy, ruptured or unruptured, by electricity? Certainly no man who is able to use the knife!

And who would to-day attempt to cure chronic salpingitis, or salpingo-oöphoritis, or old intraperitoneal adhesions, or chronic uterine displacements, by electricity? I will not deny the utility of the mild galvanic current in many cases of salpingo-oöphoritis for its soothing effect, as also in neuralgic dysmenorrhœa; or that galvanism locally applied may hasten the absorption of pelvic exudates unattended by suppuration. But a cure of an inflamed tube or ovary, a disappearance of its adhesions, or of any old intraperitoneal adhesions, is a physical impossibility by electricity or any other than a surgical procedure. The author is to be congratulated on his unfailing success in the cases treated by him with electricity. Especially would I have been pleased to see the cases of prolapsus uteri, with external and irreducible uterus, in which the "high-tension current cured every case, and caused the contraction and diminished the size of the organ, so that it was reduced and pulled back to its normal place without the use even of the hand, and solely by the action of the electric current." I devoutly wish I could have that "high-tension current" at my disposal for the cases of complete prolapsus uteri et vaginæ which I laboriously and often not too successfully endeavor to cure by a series of plastic operations. It is strange that no gynæcologist seems to have confidence in the miraculous power of electricity in these old cases of complete prolapse, which are still the opprobrium of gynæcological surgery.

But Dr. Newman's chief successes have been with fibroid tumors of the uterus. He quotes ancient history in support of his position, notably my friend the late Dr. Apostoli, who certainly deserved credit for his persistence and perseverance in pushing the claims of electricity in gynæcology, but who quite as certainly was an enthusiast, a fanatic, a "crank" on the subject. He went so far as to propose to cure a large submucous polypus, presenting through the widely dilated external os, which he showed me at his clinic in 1886, by electro-puncture, and answered my inquiry why he did not remove it by the knife or scissors, as could easily be done in ten minutes, by saying, "Why, that would not be curing it by electricity." I used galvanism, with and without a milliampere, for a number of years in uterine fibroids; I employed mostly mild currents, using intravaginal and intra-uterine blunt platinum sounds and an abdominal wet clay or sponge electrode, and all the results I achieved were a temporary arrest in growth of the tumor and an amelioration of symptoms (hemorrhage or pressure) while the treatment was continued. That I do not deny, and that in my opinion constitutes the benefit to be derived in fibroids of the uterus from Apostoli's method. A cure, a complete disappearance of the tumor, I never saw. Dr. A. Lapthorne Smith, whom Dr. Newman quotes as one of his supporters, was obliged to admit that of sixty patients with uterine fibroids whom he treated with electricity, to his own certain knowledge only two had been cured of the fibroid, for the tumor was expelled from the uterus (Am. Gyn. Trans., vol. 23, 1898). In the others, the symptoms had been relieved as the tumor had diminished in size. That a fibroid of the uterus can be inflamed and made to slough by galvano-puncture is well known. I reported several such cases with ultimate cure in my paper of 1890 (*loc. cit.*). But that is a very unsafe proceeding, and hardly to be recommended.

I believe I am known to be rather conservative as regards the removal of the fibroid uterus by abdominal section, for the reason that I do not think that the symptoms in a very large proportion of fibroids justify the risks necessarily and inevitably attending every such operation. Hence electricity would be to me a veritable boon in the treatment of such tumors, even if only to relieve the symptoms and arrest the growth. But I have of late years almost entirely discarded it, because it is too troublesome, complicated, and principally because it is too uncertain.

I have a galvanic and a faradic battery in my office, and occasionally employ them, mostly for scanty or irregular menstruation from ovarian inertia, as occurs often in anæmic or in obese, flabby women. And I consider intrauterine faradization as the method *per se* in stimulating the uterus and ovaries to increased growth and activity in amenorrhœa and sterility. But much as I esteem electricity as a therapeutic agent in nervous affections, muscular atrophy, general nervous prostration, neuroses, neuralgias of various kinds, etc., in fact, in diseases which are outside of my domain, and of which I pretend to know little, quite as much do I regret to be compelled to consider electricity a failure in gynæcology, with the above-mentioned exceptions, as compared with our present improved surgical methods for treating the majority of the affections which come under the observation of gynæcologists. I do not think, intelligently and moderately used, that it can do much harm, for instance, produce intraperitoneal adhesions as Dr. Newman quotes to have been asserted. But I do not think it does as much good as the length of treatment, its expense, and the trouble incurred should lead us to expect.

Evidently the electrotherapeutist feels differently on the subject; and that is but natural, since electricity is his special line of practice. It does not seem quite fair to intimate, as Dr. Newman substantially does, that only the cases which are surgically or otherwise incurable are referred to the electro-therapeutist, as he claims has been done in hospitals; and the method is then blamed for the failure. Surely no member of a hospital staff can be forced to treat patients referred to him by a certain method, when he knows that they are not suitable cases for that treatment.

To include the galvano-cautery under the head of therapeutic electricity, as Dr. Newman does, is incorrect, since it is the hot knife or wire which produces the therapeutic effect, not the electricity which does the heating. No one denies the utility of galvano-cautery, any more than of the Paquelin thermo-cautery, when indicated.

An explanation for the decline of electricity as a therapeutic agent in gynæcology, which I have heard hinted by electro-therapeutists, is that the gynæcologist does not know how to use electricity so as to benefit his patients. That may be true, although those of us who have used

electricity have tried faithfully and perseveringly to familiarize ourselves with the details of the batteries, currents, and instruments before using them. But that insinuation might be answered with equal justice by another, namely, that the electro-therapeutist, not being an expert gynæcologist, might fail to make a correct diagnosis of the case, both before and after his treatment, and that therefore his so-called "cures" were open to doubt, even though he might be perfectly honest in his statements.

When Dr. Newman, therefore, says, "Basing my conclusion on my own experience and on reports contained in the literature on the subject, I may say that we obtain better results from treatment by electricity than by other means," I am compelled, from my experience, to contradict him, and to question the correctness of his observations. As he himself says, "An investigation for facts and truth may not be pleasant, and it is not my desire to elicit unpleasantness; hence let us cover with professional love all differences."

However this may be, I wish I could conscientiously feel the confidence in electricity which I did when I published my papers fifteen and ten years ago. But the last ten years have wrought a great change in gynæcological practice, and where formerly tampons, applications, pessaries, and electricity were employed, to the exhaustion of patient and physician, now otherwise incurable diseases of the uterus and appendages, displacements, ectopic gestations, ruptured and unruptured (hæmatoma and hæmatocele), pelvic abscesses, etc., are rapidly and safely treated by surgical methods. That is why electricity is no longer used by gynæcologists.

PAUL F. MUNDÉ.

20 WEST FORTY-FIFTH STREET.

LETTER FROM PERU.

(From our Special Correspondent.)

VACCINATION—PREVAILING DISEASES—VITILIGO.

AREQUIPA, PERU, August 20, 1900.

WE are at present passing through our annual influenza epidemic. We have also smallpox, but that comes only every three or four years. Vaccination is gratuitous, municipal, but not compulsory. If all do not take advantage of it, it is not owing to any theoretical ideas or conscientious scruples, but to the dilatory "to-morrow" way of doing things. Sometimes, however, children, among the lower class, are not vaccinated owing to certain "astrological" ideas—a child born in a leap year or year in which there is a solar eclipse does not require vaccination, being already protected. How such ideas originated I cannot make out, and how they still exist in spite of constant proofs to the contrary is one of those mysteries appertaining to most superstitions. When I was a younger man—at the age when one knows everything with certainty—I had no doubt that vaccination should be compulsory. Now I am not so sure about it; at least, it is not the profession who should insist upon compulsory vaccination. Let the public demand it if they like.

When a man comes to me and asks "Should I have my children vaccinated?" I say, "Yes, and you also should be revaccinated." I have then more than fulfilled my duty. I am not going to seize, or get the law to seize, him and his children, and vaccinate them by force. I might with equal (or more) justice have a law passed that any one with a strangulated hernia, if irreducible, should be compelled to submit to operation. Appendicitis, glaucoma—where shall we draw the line?

I think there are two reasons (?) at the root of the resistance to forcible vaccination. First, human (especially Anglo-Saxon) nature, when ordered to do a thing, feels inclined to resist; secondly, with many there is the idea that the physicians wish compulsory vaccination so that they may be paid for it; they do not realize that if there be no vaccination the physicians will be largely the gainers. The doctors will take good care that they and their households will not get smallpox. In this respect smallpox differs from other infectious diseases or diseases bred or promoted by filthy soil, air, water, or overcrowding. These may be contracted from no fault or neglect on one's own part, but from one's neighbors' faults, and therefore it is that in these cases a central authority is required who will make all obey. It may interest some of your readers to know what diseases we have here and what do not trouble us. I give my impressions gathered during more than thirty-five years' residence. Statistics I do not give, as there are none that can be relied upon. Measles, whooping-cough, and typhus come every three or four years. As there is free traffic in contagion, they go through most of the available material in the population. Scarlet fever has not visited us. Typhoid fever is rare. Diphtheria (and croup) did not exist when I first arrived, but during the last twenty years there have been sporadic cases, at other times epidemics, particularly in some rural districts. Scrofulous necks or joints are not common. External aneurisms are very rare; the contrary is, I am told, the case in Valparaiso.

Dysentery and hepatic abscesses are rather common, as compared with Europe, but less since we changed our water supply from river to spring, a work executed by our present President. Cholera never has appeared. Yellow-fever cases have been brought here from the coast, but infection has never taken place, even though the cases were brought in the summer when the temperature does not go to 0° C. Pneumonia is at times epidemic and seems to be more fatal (case mortality) than at or near coast level. In Cuylloma, about sixteen thousand feet above sea level and twice the height of Arequipa, it seems to be even more deadly. I should like to hear the experience of some of my Californian colleagues who practise about these altitudes as to the fatality of pneumonia.

Phthisis is not common, but has, I think, become more frequent during the last twenty years, as we have easier communication—rail—with the coast, and so more patients suffering from this disease are sent here and doubtless communicate the disease to some who otherwise would have escaped. Of tubercular leprosy I have seen one case—a young negro from a coast valley.

As to hydrophobia, I have known of four cases, each separated from the others by intervals of years.

Of malaria, there are no cases here, but many cases come from the neighboring valleys. It must be remembered that Arequipa is the medical centre of a district extending toward the coast a hundred miles and more laterally, and toward the interior much more.

In some of the valleys there is a disease comparatively common, but rare here, viz., vitiligo. In Europe, Canada, and the Northern States I fancy it is a rare disease. Is it common in the Southern States? When I was a clinical clerk in the Edinburgh Royal Infirmary, I do not remember having ever seen a case in the skin ward. Most of the cases here come from the valley or have originated there, but I have seen cases here in youths and adults who had never been in the valleys. It is a general belief here that the disease is given to a person, by an enemy, in food or drink; some asserting that the substance which causes it is toad's excrement. I need hardly remark that any proof of the above is wanting. The patient is looked upon askance, people even avoiding taking his hand from fear of contagion, and often he is called "leprous," this term being loosely applied to many skin diseases. The surface attacked varies in extent from a few small patches to half or more of the body surface. I have seen an almost pure negress, aged forty-five years, whose abdomen and thorax were more white than those of a Caucasian. I cannot say how much more of her surface was affected, as I came upon it when examining her abdomen for a uterine fibroid and did not extend my surface examination farther. No connection seems to exist between the affection and the general health; often the patients are otherwise perfectly healthy and attain to a fair age. I cannot say that I have ever cured a patient, but in a very few cases I have seen a limited eruption disappear spontaneously after some months. There are some natives who pretend to be able to cure it. Some of the so-called cases of cure I have seen; they were not satisfactory, in the best of their cases what was left was superficial matrix from a destruction of the skin. They seem to use sometimes vegetable, sometimes metallic (mercurial) irritants roughly rubbed in. I have latterly been trying on small patches repeated sinapisms with some apparent effect—a diminution of the extreme whiteness of the patch and of the darkness of the surrounding border.

LIGAMENTOPAXIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your issue of October 6th publishes a description of my method of operation of "ligamentopaxis," or "round ligament ventrosuspension of the uterus," by Dr. D. Tod Gilliam, of Columbus, Ohio, which gives the details of the operation but does not mention my name.

My method was first published and illustrated in the *Centralblatt für Chirurgie*, August 21, 1897. It was also reported by Dr. C. A. von Ramdohr before the New York Obstetrical Society in the same year, and was made a graduation thesis at the University of Paris under the auspices of Poirier, Berger, Guyon, and Albarran. Garrigues' "Diseases of Women" also contains it, and the *American Journal of Obstetrics and Diseases of Women and Children*, vol. xlii., No. 8, 1900, gives a description of the original operation and some of its modifications.

I must assume that these facts were unknown to Dr. Gilliam, and that he will correct his description accordingly. Very respectfully yours,

CARL BECK, M.D.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, September 24, 1900.

GEORGE B. FOWLER, M.D., PRESIDENT.

In Memoriam: Dr. Landon Carter Gray.—DR. WILLIAM B. PRITCHARD delivered this address. He said that Dr. Gray counted on both sides a long line of distinguished ancestors. His boyhood had been spent at his father's home on Staten Island. He had graduated from Bellevue in 1873, and had begun practice in this city. In a year or two he had moved to Brooklyn, and had there developed his aptitude for the study of diseases of the nervous system. In 1890 he had been in the full vigor of health, though handicapped by an overcultured mentality. Following a third attack of la grippe in 1894 he had developed pneumonia and certain marked circulatory changes. A fourth attack of la grippe led to an endocarditis, and from that time on his health had steadily failed. He was fully cognizant of his condition, but rather than prolong his life by retirement and inactivity he deliberately and courageously chose to die in the harness. In no other sphere did Dr. Gray attain a more deserved distinction than in medico-legal work. A distinguished jurist characterized him as the model of what a medical expert witness should be. He was a type of the loyal friend and the generous foe. To him a cardinal crime was ingratitude. He was an intellectual gladiator, and the atmosphere of the intellectual arena was to him as sweet incense. He was bold to audacity; his sense of humor was keen; his ability as a teacher was striking. He possessed in a remarkable degree the faculty of organization. Of those who stood highest here in his special field today there was not one who did not bear tribute to his memory.

Demonstration of New Intravesical Instruments and Photographs.—DR. F. BIERHOFF gave this demonstration, all of the instruments being modifications of those devised by others. One of the instruments was an improved Civiale's meatotome. It was provided with a scale, a set-screw, and an indicator, so that the exact size of the meatus could be accurately gauged. A second instrument was a forceps for removing foreign bodies from the bladder. The next instrument shown was a modification of Nitze's lithotrite and foreign-body forceps. In using the original he had found that because the posterior jaw moved toward the inside of the bladder and covered the prism it was exceedingly difficult to seize and hold the foreign body. The improvement consisted in having the posterior jaw fixed and the posterior shaft fenestrated. The operator, while looking through the fenestra, could then readily seize the foreign body. Still another instrument was a cystoscopic intraprostatic incisor. It consisted of two parts—one, the cystoscope; the other, the incisor. With this instrument it was entirely feasible to select accurately the part of the prostate to be incised, and then, by rotating the instrument, to make the incision at this point. By a graduated milled head the length of the incision could be regulated to a nicety. The instrument was the joint invention of Dr. A. Freudenberg, of Berlin, and Dr. Bierhoff, and it was designed to do away with the objection that the Bottini operation had hitherto been done entirely in the dark.

A series of interesting intravesical photographs were then projected on the screen and explained.

DR. WILLIAM K. OTIS said that he had been interested in intravesical photography for the past three or four years, and hoped soon to present an instrument which could be used for such photography with ordinary plates and cystoscopes. The electric light, being always a yellow light, made it difficult to get good pictures on ordinary plates, and for the same reason yellow screens had not proved advantageous. According to his experience, a good photograph could rarely be secured with a shorter exposure than twenty seconds. The larger the cystoscope used the better. He now employed one having a circumference of 26 to 30 mm. Small telescopes gave a fairly large field, but one which is poorly illuminated. The speaker congratulated Dr. Bierhoff on his photographs, but remarked that it was asking almost too much of intravesical photography to require that these small photographs be greatly magnified and projected upon a screen. Such treatment would render even the best of such photographs almost unintelligible.

DR. H. N. VINEBERG spoke in favor of Kelly's method of cystoscopy in the female in preference to the use of the instruments of Nitze and Caspar. The Kelly instrument possessed all of the advantages and none of the disadvantages of the other instruments. He would like to ask what method was employed in removing the hair-pin from the bladder in one of the cases described. In a case of this kind coming under his own observation he had succeeded in doing this by sharply bending the foreign body before extracting it.

DR. BIERHOFF, in closing, said that he had had made in Berlin a special photographic plate, which was particularly sensitive to yellow light. This plate was circular, for use with the Nitze cystoscope. By using improved electric lamps, capable of giving a fairly white light, he had been able to get photographs of the interior of the bladder with exposures varying from five to twelve seconds. Nitze claimed to have succeeded with exposures of only three seconds, but he had used extremely powerful lamps, the use of which had been known to cause serious burns and hemorrhage. In the case of hair-pin in the bladder, the pin had been removed by rapid dilatation of the urethra under anæsthesia, followed by withdrawal of the foreign body through a large urethral speculum.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 5, 1900.

WILLIAM H. THOMSON, M.D., PRESIDENT.

Artificial Infant Feeding. Complete Report Written for the Children's Section of the Thirteenth Medical Congress.—DR. A. JACOBI presented this report. He said there were certain experiments going to show that the casein was not identical in the milk of different animals. Cow's milk contained twice as much phosphorus as did breast milk, but in the form of inorganic compounds. This fact might perhaps explain the greater tendency to rachitis in children fed on cow's milk than among those artificially fed. In his opinion, the chief advance in infant feeding had been in the more general adoption of the custom of heating the milk and the various substances mixed with it before giving it to the infant. As long as there was danger of infection of the milk with typhoid, scarlatina, tuberculosis, and similar diseases, just so long must milk be subjected to pasteurization or sterilization. For the purpose of infant feeding it was of the greatest importance that lactic-acid fermentation should be interrupted or prevented. By pasteurization all of the lactic-acid germs were not destroyed, and if there was present only one-fifth of one per cent.

of lactic acid, the milk could not be pasteurized. Perhaps it was because Dr. Koplik did not usually obtain milk in this city until sufficient time had elapsed to permit of a certain amount of lactic-acid fermentation that he was led to speak so strongly against pasteurization and in favor of sterilized milk for infants. One should not depend upon milk pasteurized or sterilized on a large scale by dairymen, for it was impossible to guarantee such an article of commerce, and there might be no alteration perceptible in the taste and smell to indicate that the milk was a dangerous article of food. The only safe way was for the milk to be sterilized or pasteurized at home daily. Last year, in the *Journal of Experimental Medicine*, Theobald Smith had called attention to the fact that by heating milk to only 140° F. tubercle bacilli were killed on an average in from five to ten minutes. In order to secure this result, however, it was necessary to prevent the formation of the membrane or "skin" on the milk by constant stirring during the heating-process. Regarding the interesting question of the modification of milk, the speaker quoted Professor Rotch as saying that the chief object should be to learn how to prescribe milk with exactitude, and then he went on to show how inconsistent it was to insist upon such exactitude in prescribing milk for infants when mother's milk, which should be our model, varied greatly in composition, not only in different individuals but in the same person at different times. The great point to remember was that in artificial feeding no routine mixture would suit any large number of cases. A certain abuse had already crept into this practice of depending on laboratory milk, for it was not uncommon for nurses to go to the laboratory and ask for a milk, and receive in response to this request a milk modified by the "bar maid" in charge in accordance with a certain printed schedule giving what a child of a certain age or size should take. Dr. Jacobi said he had known flies and cockroaches to be found in the milk coming from the laboratory, and the fact that they had been pasteurized or sterilized did not make them any the less objectionable additions to an infant's food. Another important and practical objection to laboratory milk was its great expense; it would often take the whole of a workingman's income to pay for such milk for one infant. A goodly part of the milk sugar in mother's milk had been found to be eliminated unchanged. A milk mixture containing twenty-five per cent. of milk had sufficient milk sugar in it to insure lactic-acid fermentation. It was well known that in healthy infants a large quantity of fat was eliminated from the system in the fæces, and hence he did not think it rational, under ordinary circumstances, to add cream to milk in preparing the latter for infant feeding. Moreover, the fat in cow's milk was different from that of breast milk; the emulsion was not so fine, and there was less oleic acid. His own experience in the feeding of infants had led him to reduce rather than to increase the proportion of fat for infants, and under this practice he saw no acid or fat diarrhœas. While some infants seemed to thrive on almost anything, this did not vitiate the general rule, that milk should be diluted for infants. This was particularly necessary if the infant was sick. In infantile atrophy the milk should be diluted and also reduced in quantity. Nurses and mothers often forgot that the child might cry because of thirst as well as of hunger, and that they should frequently offer it water. It had been objected that this practice led to dilatation of the stomach; but as he had never seen a case of dilatation from this cause he could not but feel that this objection was purely theoretical. In diluting milk it should be remembered that the mere addition of water would cause the formation of rather tough curds. He had always preferred to use cereal decoctions for this purpose, chiefly barley and oatmeal. He recommended that one tablespoonful be placed in one quart of water and boiled down to half a quart, and then used to dilute the infant's milk to the desired degree. Regarding the question of whether young infants could digest starch, he said that experiments had been made which showed conclusively that the saliva from the parotid of the newly born infant exerted an active diastasic influence on starch.

Dr. Henry Koplik said that the secret of infant feeding was to study each case. In doing so, it would be found that all of the recognized methods of feeding would prove useful at times. After all, the great essential was a fresh and clean milk. Sometimes everything would go along well if the cow's milk were simply diluted with a cereal; at other times this would not be sufficient, and it might be necessary to add malt—a diastase. When this was done some sick children would immediately improve, and after a time could then be put back upon the very mixture which had originally given trouble. The explanation of this was probably to be found in the fact that the physician had to deal with a sick infant and an unhealthy bowel. Scurvy was not so much the result of a particular food as of processes going on in the gut. It was seen in breast-fed infants, as well as in those fed artificially on raw milk or on milk that had been pasteurized or sterilized. He looked upon scurvy as a true toxæmia, and sterilization as only one of several causes of scurvy. In spite of the fact that pasteurized or sterilized milk was used all over this country, the American Pediatric Society had been able to find only four hundred cases of scurvy. Surely it was far better to have even this small percentage of cases of curable scurvy rather than hundreds of thousands of desperate cases of gastro-enteritis.

Dr. Henry D. Chapin said that in New York City the milk supply had improved very much in the past few years, and he believed it was in the power of the medical profession to secure still greater advance along this line. He had recently made an extensive study of the milk supply, and had been surprised to find how good it was on the whole. The most important defect noted was a lack of cleanliness. The butter fat ranged from 3.5 to five per cent. and the lactic acid about 1.15 per cent. It was perfectly well known at the present day how milk should be handled, and this being the case it was only a question of education and of money. He believed the prescribing of milk in percentages had been carried to an extreme. The proteids were calculated in the laboratory on an assumed ratio to the fats, and hence it was absurd to prescribe small fractions of percentages of proteids under these circumstances. He agreed with what Dr. Jacobi had said about the advantages of using cereals as diluents, but he also believed that there was a decided gain from the use of dextrinized gruels.

Dr. Walter Lester Carr took the same position regarding the way physicians had been misled by placing too much dependence on the printed tables supposed to represent the composition of milk. The disposition was to forget that at the bedside one was called upon to face conditions quite different from those which obtained in the laboratory.

Dr. A. Caillé sent a communication in which he expressed the belief that the most serious and common mistake in connection with infant feeding was to pin one's faith on certain routine mixtures—in other words, the physician's motto should be "individualize treatment."

Anthrax.—Excise well outside the areola surrounding the eschar. The best substitute for the knife is the actual cautery.—Warren, *Surgical Pathology and Therapeutics.*

THE AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.

Tenth Annual Meeting, Held in New York, September 25, 26, and 27, 1900.

WALTER H. WHITE, M.D., OF BOSTON, PRESIDENT.

First Day—Tuesday, September 25th.

THE meeting was called to order in the New York Academy of Medicine by the president, Dr. Walter H. White, of Boston, and the address of welcome was delivered by the acting mayor, Hon. Randolph Guggenheimer. Dr. Charles R. Dickson, of Toronto, responded to Mr. Guggenheimer. Other addresses were delivered by Dr. Louis Faugères Bishop, secretary of the Academy of Medicine, and by the Rev. Newman Lawrence.

Report of the Committee on Electrodes.—DR. CHARLES R. DICKSON, of Toronto, chairman of this committee, presented the report, and in connection therewith exhibited various electrodes. Several of those shown were made of aluminum, at the recommendation of Dr. Walter H. White, and were intended for use with the static current. One of these was a disc, three and three-fourths inches in diameter, having on its circumference twelve large rivet-heads, and provided with a handle thirteen inches long. Another, a multiple-point electrode, was made of a disc, as in the first instrument, but instead of the rivets were seven long steel points. Standard connections for electrical apparatus were exhibited, and their formal adoption by the association was recommended.

MR. R. G. BROWN, another member of the committee, presented his perforated flat electrode, made both in brass and aluminum. His plug connection was again shown, and its advantages were emphasized. He said that it had been found that aluminum was acted upon by the salt water often used to moisten electrodes. Mention was made of the use of amadou, or punk. Pads were made of this material, and were then covered on both sides with linen and carefully quilted. Made in this way they constituted excellent electrodes. He advised the use of the ordinary tinsel connecting-cords covered with small rubber tubing. This gave perfect insulation, and insured greater cleanliness and durability. In connection with bipolar electrodes it was recommended that, as a matter of uniformity, the marked terminal at the rear of the instrument should always correspond with the distal metallic portion of the electrode. The connections should be made by means of a plug and "split tube," and the electrode was preferably constructed so that it could be separated and disinfected.

The association adopted the report, including its recommendations concerning electrodes of standard size and construction.

DR. G. BETTON MASSEY, of Philadelphia, criticised the seven-point multiple electrode, contending that this number of points was altogether insufficient if one desired to guard completely against the passage of sparks. For some time he had obviated this danger by making a rosette of the metallic thread used in making tinsel cloth. A whole spoolful of this thread was wound around the fingers and then cut, thus giving a rosette made up of a very large number of fine and soft metallic points. If the patient should accidentally come in contact with this rosette, he would not be injured as he would if the electrode were made up of large, stout, steel points.

DR. R. J. NUNN, of Savannah, said that while undoubtedly tin was a valuable material for electrodes, it could be used to advantage only with currents of high voltage and low amperage, because other currents oxidized it very rapidly. He preferred thin annealed copper, which possessed the advantages without the disadvantages of block tin. Aluminum also oxidized rapidly and became brittle—a fact of which any one could readily convince himself by attempting to wear an aluminum corset during the hot months.

DR. WALTER H. WHITE, of Boston, in defence of his electrodes, said that they had been modelled after those by the French, and were intended to be used only with the French method. He had used the multiple-point electrode for five or six years, and had never known it to produce sparking. He had used with a great deal of satisfaction a mitten electrode made out of a tinsel cloth known to the trade as "armor cloth."

DR. MASSEY explained that what he had said about the multiple-point electrode used by Dr. White would not apply to the French method.

DR. FREDERICK H. MORSE, of Melrose, Mass., said that he had found that electrodes made out of ordinary asbestos cloth, such as plumbers used, were cleanly and inexpensive. They could be boiled or baked.

Electro-Therapeutic Sins.—REV. NEWMAN LAWRENCE, of Stapleton, Staten Island, read a paper with this title. He said that one of the most common of electro-therapeutic sins was the practice of this form of therapeutics by physicians who understood ordinary medicinal therapeutics, but were almost completely ignorant of electrical laws. This sin was almost on a par with that of the electrician who essayed to treat disease without having had any instruction in therapeutics. The author pointed out, by reference to well-known physical laws, the utterly fraudulent nature of those so-called electro-magnetic body appliances, which consisted of a number of small magnets and conductors which did not change their position with reference to one another. He said that he had repeatedly tested certain electric belts dependent for their action upon the moisture of the body, and he pointed out that as all of the metal plates were excited by the moisture of the body, and they could not be divided up into cells, the increase in the number of plates used in such belts simply converted the arrangement into one large plate. The concluding portion of his paper was devoted to a consideration of the all too common practice, especially prevalent among clergymen, to give testimonials about things which were not at all understood by the person thus so extravagantly singing their praises.

The paper was enthusiastically received, not only because of its impartial presentation of the subject, but because of the manly arraignment of the testimonial evil. A committee was appointed to endeavor to secure its wide publication, especially in the lay journals, where it would do much more good than in those intended exclusively for the eyes of physicians.

Discussion: Electricity in Tuberculosis and Present Modes of Treatment.—The following topics were considered:

Etiology of Tuberculosis; its Course and Termination.—DR. S. A. KNOPF, of New York, opened the discussion with this paper. He divided the etiology of tuberculosis into two parts—the sources of infection, and the causes which permitted the disease process to gain a foothold in the human economy. Undoubtedly, he said, the chief source of infection was indiscriminate expectoration. "Drop infection" or the transmission of the disease by the transportation of particles occurred, but it was comparatively rare, as it required close proximity to the diseased person. The source of infection next in importance was bovine tuberculosis. Only by uniform State laws or by Federal legislation could bovine tuberculosis be controlled. Almost all other countries had a ministry of public health, and the advantages of such a department in our national government were obvious. Tu-

berculosis might be disseminated by kissing. Tubercle bacilli had been found in cigars made by hand, owing to the saliva used to cause the final coating of the cigars to adhere. The nurses and friends of tuberculous patients were exposed to infection with the disease by inoculation. This was particularly apt to occur when they were washing out vessels soiled with tuberculous sputum. Auto-infection might arise in a tuberculous patient from a wound. Ordinarily the inhalation of air laden with tubercle bacilli did not give rise to the disease, as the epithelial cells of the upper air passages opposed the entrance of the germs, and the nasal mucus was inimical to their growth. Anything which lowered the vital resistance favored infection. The speaker declared that tuberculosis was eminently a curable disease, its natural tendency being to fibrous transformation. His belief was that in the majority of cases a fatal termination was the result of mixed infection and an intense toxæmia.

The Modern Treatment of Pulmonary Tuberculosis.—Dr. M. J. Brooks, of Stamford, Conn., read this paper (see page 563).

Electric Light as a Therapeutic Agent.—Dr. Charles O. Files, of Portland, Me., in presenting this contribution, stated that it was a recognized fact that the bacilli were destroyed by free exposure to light; hence the effort to combat the disease by exposure not only to the electric light, but to the ozone that was incidentally generated. The treatment was best carried out in an arc-light cabinet. In every case of tuberculosis that he had treated by the electric light improvement had been apparent, but it should be noted that none of these cases was in the later stages of the disease.

Electric Light; its Physiological Action and Therapeutic Value in Tuberculosis of the Throat and Lungs.—Dr. Wolff Freudenthal, of New York, presented this communication (will appear in a future issue).

Report of the Practical Value of Grotte's Method and of Others who Advertise Cures.—Dr. Egbert Le Fevre, of New York, presented this paper. He said that one year ago this method of treatment had been tried experimentally in St. Luke's Hospital, New York City. Both in-patients and out-patients were selected, and careful records were kept, including notes of the local and general physical condition, the number of tubercle bacilli, and the toxicity of these bacilli. The treatment was kept up continuously for three months. A number of cases in the first stage of pulmonary tuberculosis were treated by this method, and in none was a cure effected; moreover, the local process was not modified, the physical signs did not abate, and in two of the cases there was a distinct aggravation of the local signs after two weeks, so that the treatment was soon discontinued in these instances. In another case there was no effect on the physical signs, but the tubercle bacilli increased, and their vitality was unimpaired. Three of the cases at first showed some improvement, but no more than had been previously observed in these same individuals during their stay in the hospital under the same hygienic and dietetic treatment. A case of glandular tuberculosis did very badly under this electrical treatment; the external application of iodine, together with the electricity, causing violent irritation, and finally necessitating a surgical operation. In this patient, with the breaking down of the glands there was rapid softening of the lung, and the disease then ran a very rapid course. Cases in the so-called second stage — *i.e.*, when there was beginning softening — were not improved by the electrical treatment, there being no perceptible effect on the bacilli or on the septic infection. In the advanced cases the treatment apparently did harm. In one case which had been in the wards for eighteen months, and in which the process had been apparently arrested for a considerable time, there was a rapid breaking down of the lungs after six weeks of the treatment, and the patient died four months after the treatment had been discontinued. Regarding the Grotte method, Dr. Le Fevre said that in the three months' trial just described a static machine had been used in connection with the apparatus invented by M. Grotte. In this machine there was supposed to be formalin, and his claim was that it was acted on by the electric current and by the latter carried into the patient. The patient was put on an insulated stool, and a towel wrung out of a mild solution of formalin was spread upon the chest, and the current then passed. A solution of iodine in spirits of camphor was also painted over the portions of the chest corresponding to the diseased areas of the lung. It was worthy of note that the pathologist of the hospital could not detect any iodine in the patient's secretions in spite of the claims of the inventor that it was carried into the system by cataphoresis.

The Treatment of Tuberculosis by Means of Transfusion of Antiseptics by Means of Static Currents of High and Low Tension.—Dr. J. L. Hatch, of New York, said that since last winter he had constantly seen some of Grotte's patients, and the results of the treatment in them, as well as in some of his own cases, had surprised and pleased him.

Dr. G. Betton Massey, of Philadelphia, opened the general discussion by describing his method of treating tuberculous glands of the neck. An opening was made into the gland large enough to admit a gold electrode not much larger than a hypodermic needle. This electrode was amalgamated at its tip, and through it a globule was injected. An electric current of from three to ten milliamperes was used, and by electrolysis the tissues were asepticized by the formation of the oxychloride of mercury. Cases were cited to prove the good effect of this treatment, and the speaker urged that this method be employed for the purpose of destroying the tubercle bacilli in cases of local tuberculosis in almost any part of the body except possibly the cranium, thorax, and abdomen. He believed it to be both a quick and an efficient method of improving the local and general condition.

Dr. Robert Reyburn, of Washington, D. C., said it was not at all essential to use a gold needle, as he had successfully conducted a similar method of treatment, using an iron needle. He was of the opinion that it was much better to operate without making an opening into the skin, as the latter would needlessly open up a possible channel of infection.

Dr. William J. Morton, of New York, said that Dr. Massey deserved credit for adding mercury to the list of substances that were serviceable in carrying out that useful method of treatment introduced by Gautier under the name of metallic electrolysis. At one time he had been an enthusiastic advocate of metallic electrolysis, but had sobered down somewhat after making some experiments to determine the extent to which the various metals used as electrodes could be driven into the tissues by the electric current. He had never been able to make this diffusion extend farther than one-fourth of an inch, and even to do this it had been necessary to use a stronger current than was desirable. Regarding the Grotte treatment of consumption, Dr. Morton said that he had visited St. Luke's Hospital with a view of learning by personal inspection something regarding this method. He had seen on one side of the room an excellent static machine of American manufacture, and on the opposite side a cumbersome French machine having ebonite plates. He could vouch for the vigor with which the electricity was applied, for the sparks were flying freely, but, to his surprise, on testing the French machine, which he

was informed was the one depended upon almost entirely for the essential part of the treatment—the cataphoresis—he could secure from it no sparks whatever. This observation had very naturally aroused his suspicions, and he hoped the association would appoint a committee, and instruct it to search for definite proof that formalin vapor, or any similar substance, could be made to enter the human system by the aid of electricity. Its effect on disease could then be determined by physicians at the bedside. He wished to be perfectly fair to all concerned, and for that reason the committee should inquire carefully into the electro-physics of the Grotte method. M. Grotte should prove that iodine, or the products of formaldehyde, could be really introduced into the healthy human system in this way.

Dr. Le Fevre, in closing the discussion, said that when the pathologist of St. Luke's Hospital had reported that he had been unable to prove that either the formalin or the iodine had been introduced into the patient's system, M. Grotte objected to the person carrying out the investigation, on the ground that he was incompetent. Grotte's own chemist was then allowed to conduct an investigation, but he too failed to prove that any medicinal substance had been introduced into the system by the treatment. The treatment had been abandoned because apparently useless and because the claims of its inventor had not been substantiated. It was hardly necessary to add that the physicians of the hospital had conducted this investigation with all sincerity and in an impartial and scientific spirit.

A committee, consisting of Drs. William J. Morton, Robert Newman, and Emil Heuel, of New York City, was then appointed to investigate the electro-physics of the Grotte method.

A Plea for the Better Application of Electricity in Diseases.—Dr. J. Griffith Davis, of New York, in this paper cited various cases to illustrate the importance of studying well the mode of application of electricity best suited to the individual patient.

Some New Appliances for X-Ray Work.—Mr. E. W. Caldwell, E.E., of New York, made this exhibit. The first appliance shown was an improved stand and holder for the *x*-ray tube. The latter, instead of being held with a screw-clamp rigidly—a method fraught with danger to the tube—was securely held in a forked piece of wood by easily graduated pressure made by a band and a small coil spring. A most interesting and ingenious device was a wooden shelf or adjustable table for supporting the arm firmly, no matter what its position. This rest was supported on a ball-and-socket joint, and by means of two or three simple attachments the arm, forearm, and hand could be prevented from twitching or trembling, and the photographic plate could be readily placed parallel to the condyles. Considerable difficulty was often experienced in obtaining good *x*-ray photographs of the pelvic and hip joint. To facilitate getting the two limbs parallel to each other and to the plate, each limb was strapped to a small wooden table, and the latter were joined by levers in such a way that when the injured limb was put in the desired position and clamped, the well limb would be parallel to the injured one. The speaker said that in taking *x*-ray photographs the plate was often injured by the moisture of the person's body. The best and cleanest way of preventing this was by interposing a thin sheet of celluloid, such as could be procured at artists' supply stores. This material was clean and waterproof, and was very transparent to the *x*-ray.

Dr. Charles O. Files, of Portland, Me., asked if it were possible in most cases to secure a good picture of the head of the femur. He had tried this a good many times, and with indifferent results when there was much adipose tissue. He was under the impression that one could not get a good picture of the head of the femur under such circumstances.

Mr. Caldwell replied that it was always difficult to get such a picture, even with a young and lean subject, but in the majority of cases it was possible to get one sufficiently good to show whether there was present a fracture or any extensive necrosis of the head of the femur or of the acetabulum. With a fleshy subject having small bones it was decidedly difficult. The best picture of this kind that he had made had been of a man weighing one hundred and fifty pounds, and this had required an exposure of six minutes. The longest exposure which he used in such cases was fifteen minutes, though with children one minute would often suffice. In most of his work the *x*-ray tube had been excited with the coil, and he preferred this to the static machine, as he found that he could obtain certain results with the coil that he could not with the static machine. He would admit, however, that some of the most beautiful radiographs that he had seen had been made with the static machine. For the extremities the static machine was excellent, and perhaps gave rather better definition than the coil, but for the hip joint he personally preferred the coil.

Combined Electrization or Galvano-Faradization.—Dr. A. D. Rockwell, of New York, read a paper with this title. He said that by the term galvano-faradization was meant the simultaneous application with the same electrodes of the galvanic and faradic currents. He believed that the contractile fibre cells were more powerfully excited by the interrupted or high-frequency currents, and that there was greater stimulation of waste and repair than when the galvanic current alone was used. It had always seemed to him that the combination of these currents was as rational as the combination of our medicines in prescriptions. His experience had fully confirmed this view. The faradic current alone had very little effect on osmosis; the galvanic current, on the other hand, stimulated osmotic action to a great degree. This was still more marked by combining the two currents. When this was done, heat production was also increased. The physiological action of electricity was shown chiefly through its influence on secretion, excretion, and absorption. All forms of electricity would relieve certain painful conditions, one succeeding when the others failed, and *vice versa*. Parts sensitive to pressure, barring the hyperæsthesia of hysteria, were, as a rule, more favorably affected by the galvanic than by the faradic current. The same relief from pain was often not observed from these currents when combined. The use of the combined currents was especially valuable in the treatment of spasmodic conditions, particularly local ones. The symptoms of exophthalmic goitre were more readily controlled by the combined than by the simple electrization.

Dr. G. Betton Massey said that the galvanic and faradic batteries could be easily combined by connecting the negative of the galvanic with the positive of the faradic battery, and setting both in action, preferably controlled by a controller. There was a distinct value to galvano-faradic electrization, which was explicable on a consideration of the subject of electrotonus. Years ago Waller had shown that at the negative pole the galvanic current would cause the faradic current to be more active, and at the positive pole less active.

Mr. R. G. Brown said that he was unable to understand how it was possible to use this so-called combined electrization, for the one must short-circuit through the other. This remark gave rise to a lengthy discussion, which was finally cut short by lack of time and before a definite agreement of opinion had been reached.

Gleanings in the Field of Electro-Therapeutics.—Dr. Charles O. Files, of Portland, Me., read this suggestive paper. The first case reported was one of double amputation of the thigh, done about one hour after the crushing of the limbs in a railroad accident. During the operation the patient suddenly succumbed to the combined shock of the injury and the operation, and appeared to be dead on the table. The prompt application of a galvanic current, one pole being put to the epigastrium and the other to the base of the brain, revived the patient almost immediately. It was, however, necessary to resort to electrization at short intervals for nearly three weeks, as the heart frequently flagged. Every surgeon who saw the case during the first fortnight expressed the opinion that the prognosis was practically hopeless. The man completely recovered. Another case mentioned was one in which most gratifying improvement followed electrical treatment and massage in a case of incipient tuberculosis. For many years the author had found electricity a most valuable ally as a hypnotic, and in many inveterate cases of facial neuralgia, even those which had persisted after repeated surgical operations on the nerves and ganglia.

Second Day—Wednesday, September 26th.

Electricity in Gynæcology, and the Present Reluctance of Gynæcologists to Use Electricity.—This was the general subject for discussion.

The General Office Work of a Gynæcologist.—Dr. Fred. H. Morse, of Melrose, Mass., read a paper with this title. He said that nowhere had electricity a greater range of usefulness than in gynæcological work. The man who could see no other treatment than surgical for pelvic adhesions and sore ovaries would save much suffering and unnecessary operating by the intelligent and proper use of electricity. Electricity was invaluable in making the diagnosis when there was a deep-seated pus formation. In metritis, endometritis, subinvolution, uterine displacement, ovarian neuralgia, painful menstruation, electrical treatment was most satisfactory. In acute inflammatory conditions electrical treatment was not contraindicated, but special care was requisite in its application. The intensity of the current, the size and nature of the electrode, and the length of the treatment must all be carefully considered. In most cases such treatment could be carried out properly in the physician's office. A reliable battery and amperemeter and a good high-tension faradic battery were absolutely essential. He preferred asbestos cloth for the material of which the distributing electrode was constructed. Ordinarily the external electrodes employed were too small.

The Morton Wave Current—A Valuable Addition in Electro-Therapeutics.—Dr. W. B. Snow, of Atlanta, Ga., sent a paper with this title. In his absence the paper was read by Dr. Dickson. The author stated that the wave current was unique in many of its characteristics. In the first place, it was the only current administered from but one side of the generator; (2) it was the only current in which the alternations were of charge and discharge; (3) it was the only current administered to the patient while insulated; (4) it was the only current with high potential that could be passed to and fro through the body with little discomfort; (5) it was the only current with the passage of which the patient received general electrization, the surges of the current passing through the tissues of the body. These properties of the wave current made it the choice of all electrical currents if there was any virtue in electricity, for it permitted the use of the highest possible electromotive force upon the patient. The fact that it penetrated every part of the body made it unexcelled. It was so controllable that it might be applied to the eye. One million volts of this wave current might be applied with safety, and with but little discomfort to the patient. The physiological actions of this current were the result of: (1) The surges of the current to and fro, and (2) the intense vibratory and peculiar local electrical effects. The constitutional effects were: (1) Marked lowering of arterial tension; (2) lessened frequency of the heart's action and increased volume of pulse; (3) increased oxidation and metabolic activity; (4) marked diminution of nervous irritability with sense of drowsiness; and (5) a sense of fatigue if the sitting was too prolonged. The current was said to be absolutely harmless and a powerful tonic. So far as had been determined, polarity did not affect the result. The local effects were: (1) A sense of vibration, marked over the muscles when there was little underlying fat, and by rhythmic contractions; (2) physiological tetanus; (3) the sedation of pain and nervous irritability by prolonged and gradually increased electromotive force as toleration permitted; (4) an antispasmodic action; (5) stimulation of the glands beneath the electrodes to more active secretion; (6) local congestion and hyperæmia were relieved when not due to specific poison or to necrosis. Metabolism was most active beneath the electrode. As a general rule, the treatment gave better results than sparks except where the small muscles contracted too painfully, as, for instance, in the hands in cases of rheumatoid arthritis. All atonic conditions and chronic menstrual disorders were relieved by treatment with this current. To obtain the best tonic effect, a long block-tin electrode should be placed under the clothing and over the vertebral column, and a one-inch spark-gap employed. Most cases of neuralgia not due to pressure or to specific poison were relieved by a few treatments. Most cases of sciatica could be successfully managed by daily treatments. Few conditions required treatment at shorter intervals than twelve hours. A most important factor in such treatment was what was termed by the author "bridging," *i.e.*, a repetition of the treatment before the pain had had time to become severe again. It was the only current in which the alternations were of charge and discharge. For sprains and bruises the application of the wave current was the treatment *par excellence*.

The Nervous Disorders Peculiar to Women.—Dr. G. Betton Massey, of Philadelphia, in this paper discussed more particularly the relation of neurasthenia to these disorders, and the frequency with which affections within the abdomen underlay the neurasthenia. He pointed out the frequent need for well-regulated and properly directed activity as opposed to the notion of absolute rest.

Use of the Continuous Current and Electrolysis.—Dr. Robert Newman, of New York, presented this paper (see page 486).

Dr. Massey said that this field was less attractive and less remunerative than that of operative surgery, and hence the reluctance of gynæcologists to use electricity. He quoted Dr. Thaddeus Reamy, of Cincinnati, as saying that in the State of Ohio many physicians by the use of electricity were now keeping their patients in their own hands, and protecting them from the specialists in the large cities.

Dr. Reyburn remarked that one reason for their reluctance was that they were quite often ignorant of the laws of electricity and hence could not use electrical treatment with advantage.

Dr. William J. Morton thought it was time for electro-therapeutists to admit that they sometimes adhered too fondly to their favorite method, and refrained from the use of the knife sometimes when perhaps it might be better. Extremes should be avoided.

Dr. Lucy Hall-Brown said that another reason

why gynæcologists were loath to employ electricity in their practice was that it required such a large amount of apparatus and attendance, and consumed so much time; however, she could not see how any gynæcologist could be really conscientious in his work and wholly refrain from the use of electricity. She had had three cases of fibroid tumors in which complete hysterectomy had been done. One of these patients had made a good recovery and had remained well; another had apparently recovered, but had later developed melancholia and had committed suicide three months after operation; the third had died three days after operation—not a very excellent showing for the operative treatment.

Dr. Reyburn said he had treated about half a dozen cases of fibroids by the use of electricity. In all of them there had been improvement, and three had been practically cured.

Several other members took part in the discussion, expressing views similar to the foregoing regarding the operating gynæcologists and their methods of practice.

Spark-Gap Currents, viz.: Franklinic Interrupted, Static Induced, and Wave Currents.—Dr. William J. Morton, of New York, discussed this subject. In his opinion, the wave current, or as he preferred to call it, the "displacement current," presented more advantages than either the franklinic or static induced current. From the standpoint of the electro-therapeutist he believed this wave current embodied all that could be obtained from an electro-static machine in current form. He made use of it in neurasthenia and in all cases when the object was to improve the general nutrition. One of its most remarkable effects was the production of analgesia or anæsthesia. It was more pleasant to take and more diffusive than the static induced current and was quite as easily localized.

Dr. Hall-Brown spoke more especially concerning the technique that she had made use of in treating patients with the wave current. The loud noise made by the static machine she had succeeded in reducing very materially by inserting the terminals of the machine in corks at either end of a very large glass tube. In order to insure good contact between the electrode and the patient she made use of block-tin strips, and carried these down along the spine, under the clothing, very easily by the use of a director made of a piece of hard rubber not unlike a thin ruler in appearance. The strips of tin should be kept very smooth, and this was accomplished by passing over them the "squeegee" roller sold in photographic shops. She had employed this current quite extensively in the treatment of neurasthenia and neuralgia. A study of the urine showed quite conclusively the profound effect of the current on glandular activity, and gave a valuable hint as to why it proved so useful in the treatment of neurasthenia. For gynæcological work she made use of a wooden table insulated by screwing glass telegraph insulators on to the legs. The current was conveyed into the room by a wire insulated with rubber and enclosed in a glass tube.

Dr. C. R. Dickson, of Toronto, said that the wave current had proved of great value in his hands in the treatment of sciatica and peripheral neuritis.

Dr. Margaret A. Cleaves, of New York, attributed the great value of this wave current to the fact that with it one was able to expend a greater amount of energy within the tissues of the body without causing discomfort. In this way profound changes of nutrition were set up. It had seemed to her that the method was indicated more especially in pathological processes of rather long standing. She had used it in neuritis, rheumatoid arthritis, neurasthenia, and, in gynæcology, especially in prolapsus, and had found it an agent of exceeding great value.

Dr. Walter H. White, of Boston, remarked that he had been using this current for about a year past in neurotic conditions, and with good success.

On Methods of Generating and Transforming Electric Currents for Therapeutic Uses.—Mr. Charles T. Child, E.E., technical editor of the *Electrical Review*, sent a communication with this title. In it he said that what was ordinarily known as the direct current was a special case of the alternating current in which the frequency was reduced to zero. One must know the electromotive force or tension (measured in volts) and the volume of current flowing, the latter being measured in amperes or milliamperes. For therapeutic purposes the maximum of pressure was sixty or seventy volts. There were two ways in general use for producing the direct current for therapeutic purposes, one the familiar battery, and the other by the cutting down of currents of high voltage. Although the battery had recently celebrated its centennial it was yet far from a state of perfection. The so-called dry battery was useful only for small currents and for short periods. For the running of motors and cauteries storage batteries were best. The reduction of high-pressure currents for therapeutic purposes was done most simply by employing a shunt around a resistance, such as coils of wire or incandescent lamps. In order to avoid abrupt stops, the resistance coil must be very finely subdivided, or so arranged that contact could be made with it at any point of its length. The action of static machines depended upon the principle of the familiar electrophorus. They generated potentials up to several hundred thousand volts. The complexity of action of the static spark was astonishing in view of its apparent simplicity. To produce the static induced current two condensers or Leyden jars were attached to the terminals of the machine. A brief description was given of the modern methods of producing induced currents, and emphasis was laid on the part played by interrupters, particularly the fluid interrupter.

Illustrations of the Value of the Cataphoric Method in Cancer.—Dr. G. Betton Massey, of Philadelphia, discussed this subject. He said that he had recently published statistics showing that there could be no doubt that cancer was very decidedly on the increase. He declared that cancer was now known to be a curable disease. His method of treatment consisted in driving the salts of mercury into the cancer under the action of a heavy electric current. Of course, cataphoresis was well known, but the plan of using mercury in this way was original with him. As the method was painful, the patient should be etherized and placed on a large negative electrode consisting of a leaden plate covered with heavy pads. The active electrode was made of a tube of gold the tip of which was amalgamated. A current of three hundred or four hundred milliamperes was used, and mercury was injected through the hollow electrode. Within ten minutes the tumor began to blanch. The operation was kept up sometimes for two hours or more, and resulted in extensive necrosis of tissue which had been asepticized by the penetration of the mercury. An inodorous slough separated in from one to three weeks. This was a bloodless method of destroying an accessible growth, and at the same time sterilizing its immediate neighborhood. Dr. Massey said he had used the method in 37 cases, and of these 11 had been successes. Of this number of cases, 22 were metastatic at the time of beginning the treatment, showing that the treatment had been begun too late. Of the 37 cases, 2 were fatal from causes traceable to the treatment, and avoidable in the future. One was that of a woman dying of carcinoma of the tonsil. She took ether badly and died before the full current could be turned on. He had used as much as four hundred

milliamperes about the neck, and as much as six hundred immediately over the heart, but such currents must be used with great care. It was not intended, of course, that it should take the place of the knife in all cases, but in many instances it would be a more convenient means than the knife. It afforded an excellent opportunity of reaching the earliest manifestations of cancer, or of treating very promptly the first recurrences after a cutting operation.

Dr. Morton said that while reasonable success had been met with in the use of this method, he was frank to say that he had never felt like using such heavy currents. If by any inadvertence the patient should move there would be variation of potential, and it must be remembered that a variation of only two milliamperes about the head would produce severe vertigo. He had known twenty-five milliamperes to produce a momentary syncope.

Dr. A. D. Rockwell, of New York, suggested that it might be well in a case of large cancerous tumor to introduce the mercury into the base, thus diminishing the amount of sloughing.

Dr. Morton remarked that when these metals were oxidized at the positive pole it was at the expense of the electrolyte, so that when the tissues became dry during the electrolysis—in other words deficient in water, oxygen, and sodium—the process went on slowly. To obviate this he had been in the habit of using a hollow platinum needle, with the aid of which he injected a solution of chloride of sodium, thus renewing the supply of electrolytic material.

Dr. Massey, in closing, urged as an additional advantage of the method, that cancer of an organ could be extirpated without necessitating the removal of all of the organ. The method was particularly suited to cases of carcinoma of the cervix uteri. The chief danger from using these heavy currents was from interference with respiration or with the heart's action. In these etherized patients syncope amounted to nothing, and the operator was justified in taking some risk because of the desperate nature of cancer.

The Causes of Some Cases of Neurasthenia, and their Treatment.—Dr. Francis B. Bishop, of Washington, D. C., read this paper. He said he had been in the habit of having a quantitative analysis made of the daily amount of urea and phosphates in cases of neurasthenia, and he had learned in this way that in neurasthenics there was quite commonly a diminution of the daily quantity of urea and an excess of phosphates. The muscular tissue formed about forty-two per cent. of the body weight, and seemed to be the chief seat of metabolism. Muscular exercise increased the output of urea, but not until the day after the exercise had been taken, thus showing that certain chemical changes must take place before the urea was formed and excreted. The object of treatment should be to promote these chemical changes by muscular exercise. Ordinary muscular exercise was good in its way, but was followed by fatigue, and these persons were already fatigued. For this reason he made use of electricity. He began with a mild galvanic current to stimulate the cells of the brain and spinal cord. This was followed by general galvanization, and then by general faradization according to the method of Dr. Rockwell. General galvanization was applied by having the patient lie upon a pad twelve inches square placed under the back, and passing a hand electrode over the different muscles. Lastly the patient received treatment for about fifteen minutes in his ozone cage, receiving a mild spray during this time. This cage had proved particularly beneficial in cases requiring a soothing effect and gentle stimulation. Many functional nervous troubles could be successfully treated with his ozone cage.

Dr. Rockwell spoke of the two principal types of neurasthenia, the hereditary and the acquired, and said it was difficult to treat neurasthenics without at least occasionally using drugs. He had found the bromides and cannabis indica especially valuable.

Dr. D. R. Brower, of Chicago, remarked that in many of his neurasthenics he had found dilatation of the stomach, while in others there had been an impaction in the colon. He was convinced that there was an intimate relation between the state of the abdominal cavity and neurasthenia.

Dr. S. Fairweather Wilson, of Montreal, mentioned two or three cases of neurasthenia that had been marked by renal insufficiency. In addition to hydropathic measures, he had treated them with static electricity, using the head breeze and small sparks over the abdomen, and had in each instance been rewarded by seeing the patients recover promptly.

Dr. Cleaves said that when certain neurasthenics seemed to require something more than the convective discharge she was in the habit of using the galvanic current in the form of the vaginal hydro-electric douche. Dr. Bishop's "ozone cage" acted like covering the patient with a large crown electrode, so that the discharge was through the whole body instead of simply from the head. Of course, a large quantity of ozone was generated, but the name ozone cage was perhaps a little misleading, as directing the attention away from the main point.

X-Ray Photography.—Dr. E. R. Corson, of Savannah, read a paper on this topic. He expressed the opinion that the most important thing was to have a generator which would furnish powerful *x*-rays. A skiagraph giving mere bone outlines was certainly not satisfactory, and unless the *x*-rays were powerful enough to penetrate the bone, details could not be properly brought out, no matter how great one's photographic skill. The mere length of the spark did not indicate the efficiency of an *x*-ray apparatus. By increasing enormously the number of interruptions the quantity of current passing through the tubes was also augmented, and the efficiency of the apparatus proportionately increased. The author recommended the use of a coil giving a spark of only eight or ten inches, and all of the current the *x*-ray tube would stand. It was also recommended that a hydrochinone developer be employed, and that all negatives, no matter how strong, be intensified after development. His negatives were usually so black that they were difficult to print, but when printed they showed no flesh, and gave sharp contrasts. The object was to give as clearly as possible the internal bony structure.

Third Day—Thursday, September 27th.

Electricity in Brain Failures.—Dr. D. R. Brower, of Chicago, read a paper with this title. He attributed the frequency of cerebral neurasthenia at the present time to the almost universal condition of unrest, the keenness of competition, the drifting away from the authorities of the past, and not a little to "Young America" and "the new woman." In his experience it was rare not to find this disease associated with disorder of the intestinal tract, or with dilatation of the stomach. He recommended most earnestly intragastric electrization, claiming that the treatment could be readily carried out by the patient himself. The séances should be daily, and of about five minutes' duration. Applications through the abdominal wall were far less efficient than with the Einhorn gastric electrode. The applications in any case should be made three or four hours after a meal. Of course, proper attention should be paid to the diet, but in addition the physician should resort to intestinal faradization. Galvanization of the brain was also necessary, and was entirely feasible, as had been abundantly

proved by Erb and other eminent and trustworthy observers. The electrodes which he used were three by seven inches, one being placed on the forehead, and the other at the nucha. The general character of the mental phenomena determined the polarity. If the case was one of general depression, the negative pole was placed at the forehead, but if the case was characterized by excitement, the positive pole was placed there. He rarely exceeded a current strength of two milliamperes, and often not more than one milliampere. It should be continued for two minutes, and then be followed by transverse galvanization, using the same electrodes and a current of one to one and one-half milliamperes for five minutes. This should be followed by bulbar galvanization, the positive electrode being placed at the nucha while the negative was moved up and down over the cervical sympathetic on both sides without breaking the current. The duration of this treatment should be five minutes. This application should be followed by static insulation from a machine giving a ten-inch spark. This latter application should be made daily for the first ten days, and then on alternate days. Special stress was laid on the great advantage of using currents of low amperage and protracted applications in the cerebral galvanization of neurasthenics.

Electro-Therapy of Insanity.—Dr. Alfred T. Livingston, of Jamestown, N. Y., read this paper. He said that it was now about nineteen years since he had first used electricity in the treatment of mental disorder. He had at first proposed this to the eminent consultant, the late Dr. John P. Gray, of Utica, but the latter had opposed the treatment very vigorously. However, he had ultimately tried it on a patient, a woman of thirty years suffering from acute melancholia. The first application showed plainly the calmative effect of the galvanic current when applied to the centres connected with the brain. In the course of a few weeks the patient was thoroughly restored to health. He had since used it frequently, and had been greatly pleased with its calming action. Inquiry both at home and abroad had shown that this use of electricity was almost unknown. The author closed with an earnest plea for larger medical staffs in our insane hospitals, and for better treatment of insanity in the earlier stages, thus curing many patients now allowed to become chronic or incurable. The treatment advocated was founded on the theory that insanity was largely dependent, in the first instance, upon circulatory changes in the brain. As a rule, the current should be made to pass through the nervous centre related to the part affected. The method of application consisted in directing the galvanic current to the three pairs of the sympathetic cervical ganglia, beginning and ending with the lower pair, and using small hand electrodes. A current of ten to fifteen milliamperes was used on the lower, eight or ten on the second, and from five to eight on the upper pair. The electrodes were slid along without producing any break in the current. He was of the opinion that in any case of insanity the effort should be made to correct all disordered bodily functions, with the object of aiding mental recovery.

Dr. Massey said that static electricity seemed to him to offer much hope of relief in this class of cases.

Dr. E. B. Silvers, of Rahway, said that in alcoholic patients the use of cannabis indica internally, and electricity externally, had succeeded very well in his hands, and the method had been tried with good results in the Trenton asylum.

Dr. W. E. Ford, of Utica, said that the ranks of the insane were recruited from neurasthenics who had gone from one physician to another for months or even years, without the gravity of their condition being appreciated, or without receiving benefit because the physicians did not care to give them sufficient attention. He was positive that electricity always did these persons some good. The mild stage of dementia which followed serious neurasthenia was the same mild condition of dementia which came after a mild attack of acute melancholia. The relaxed condition of the capillaries seen in these patients could be immensely improved by electrical treatment— often much more so than by drugs.

Dr. Brower remarked that he had found that many neurasthenics among the poorer classes could be treated very satisfactorily in general hospitals.

Dr. William J. Morton was of the opinion that all these neurasthenics should be cared for by the general practitioner, but he had very little respect for the treatment ordinarily meted out to these poor neurasthenics. The wave current was valuable in these cases because it soothed the nervous irritability and promoted sleep. Much of his success in the treatment of these cases he veritably believed arose from stopping them from taking the various tonics prescribed for them by general practitioners who should know better. Strychnine, iron, and the hypophosphites were the favorite remedies. If such medication were stopped, and the patient was told to take plenty of rest, abstain from starchy foods, and live chiefly on meats and salads, the result would almost always be satisfactory.

Dr. Francis B. Bishop said that it had been his experience that neurasthenics were very prone to commit suicide, yielding to the influence of suddenly developed delusions. He was accustomed to apply the galvanic current to the sympathetic, as outlined in the paper, and, in addition, to make use of the static spray, surrounding the patient with what he had called the "ozone cage." This application was usually very soothing.

Officers Elected.—The election of officers of the association for the ensuing year resulted as follows: *President*, Dr. Ernest Wende, of Buffalo; *First Vice-President*, Dr. Fred. H. Morse, of Melrose, Mass.; *Second Vice-President*, Dr. D. R. Brower, of Chicago; *Secretary*, Dr. George E. Bill, of Harrisburg; *Treasurer*, Dr. R. J. Nunn, of Savannah. The next annual meeting will be held in Buffalo on September 9, 10, and 11, 1901.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 6, 1900:

	Cases.	Deaths.
Tuberculosis	261	152
Typhoid fever	104	15
Scarlet fever	87	2
Measles	30	4
Diphtheria	210	19
Laryngeal diphtheria (croup)	6	2
Cerebro-spinal meningitis	0	0

An Alleged Danger in Porcelain Ware.—The United States consul at Mentz quotes, in a report to the State Department at Washington, certain remarks of a journal published at Frankfort-on-the-Main regarding the silver-mounted porcelain cups, jars, vases, etc., which have recently been placed upon the market. The silver on these articles, the writer states, is applied by an electrical process, in baths which contain very large quantities of potassium cyanide. As glazed wares have innumerable hairlike cracks, this poison enters these cracks, and the articles become a menace

to the health of anybody using them, since it is impossible in the course of manufacture to remove this poisonous residuum. Only a short time ago, it is asserted, a nearly fatal case of poisoning resulted from the use of such ware.

A Paris Sewage Farm.—On August 12th some three hundred members of the Congress of Hygiene and Demography were conveyed by special train to the plains of Achères situated on the banks of the Seine close to the forest of St. Germain. This estate measures 10 km. in length and 1 km. in width. It is irrigated throughout with the crude sewage of Paris. A writer in *The Lancet* says that, in 1895, when the sewage from Paris was just beginning to arrive, the greater part of this plain seemed like a vast desert. The small brushwood had been cleared away and nothing had yet grown in its stead. "The contrast to-day is most remarkable. The barren plain is now verdant with luxurious vegetation. Beetroot is growing over a large part of the ground, but there are also many fields rich with golden grain. The avenues are planted with trees, mostly walnut. Of course they are still young and small, but they are healthy and flourishing. The greater part of the land is let out to cultivators, but the municipality has kept a portion in its own hands for experimental purposes and to lay out a few ornamental parks, and to plant orchards. It was at these spots that the members of the congress stopped so as to stroll among the flower-beds, admire the peaches and other fruits ripening on the trees, and above all to visit the ornamental waters; these were as clear as crystal. Fish darted rapidly about, and as the water came out of the earth in little jets glasses were filled and the water was eagerly drunk by nearly all the visitors. Yet this was neither rain-water nor spring-water: it was the water of the Paris sewers. What this meant was evident to all, for close by on the surface of the soil in countless little drains the black, foul sewage was exposed to view. But having fed the plants and having passed through more than six feet of sandy soil the water collected at the lower levels is found to be quite free from the sewage. The sewage, which contained 11,750,000 bacteria per cubic centimetre, retained but 2,350 bacteria in one part of the estate and only 188 in another part—that is, of course, after it had filtered through the soil. The purified sewage water at Achères is more free from bacteria than is usually the case with good spring water. In regard to organic matter, when the amount extracted from the sewage weighed 34.9 gm., after passing through the soil the same bulk of water retained only 1.8 gm." The sewage farms of Paris now cover an area of 5,000 hectares (approximately 12,355 acres), consisting of 900 hectares at Gennevilliers, 1,000 hectares at Achères, 2,150 hectares at Méry-Pierrelaye, and 950 hectares at Carrières-Triel.

Surgical Treatment of Hydatid Cysts of the Liver.—Prof. Thomas Jonnesco, of Bucharest, said in a paper read at the recent International Medical Congress at Paris, that at the present time four kinds of operations are performed for hydatid cysts of the liver: (1) Puncture, whether followed by parasiticide injections or not; (2) marsupialization; (3) incision followed by evacuation and suture of the cyst; (4) enucleation and extirpation of the cyst. The last operation, which is ideal, is so rarely applicable that it can hardly be taken into account unless as an exceptional intervention. Puncture should be given up as uncertain and even dangerous. Marsupialization, in view of the duration of the treatment, remains an operation of necessity applicable to suppurating cysts and to those in which the calcified adventitia no longer allows retraction of the pouch to take place. The operation of choice consists in incision of the cyst which is emptied of its liquid contents, daughter cysts, and germinal membrane, and suture. The pouch is left without drainage or fixation of the cyst to the abdominal wall. Jonnesco has operated in six cases of cysts, varying in size from that of a man's fist to a diameter of 20 or 30 cm., and always with success. The effusion of bile into the cyst is not a contraindication.

Cape Town Verdict on Food Preservatives.—Cape Town seems determined to have undrugged food, and recently a dealer has been fined for selling milk containing formaldehyde. Mr. C. F. Juritz, public analyst for Cape Town, has rightly described formaldehyde as a strong disinfectant which impaired the nutritious value of food, making it less digestible. Its use minimized the necessity of cleanliness and made it possible to sell old milk instead of new.—*British Food Journal.*

A Death from Sulfonal was reported recently in the daily papers. The deceased had taken 440 grains of the drug.

Medical Fees in China.—As Chinese affairs are very much to the fore just now, it may be interesting to mention that a doctor's fee is perhaps the smallest in the world, ranging from *2d.* to *5d.*, but this can be accounted for by the fact that any one can practise, it being necessary only to hang out a sign intimating the fact that the owner has some medical knowledge; and, although these are very numerous, they are, as a body, the most respected men in China.—*The Medical Press.*

The Medicine Habit in Great Britain.—George R. Sims, better known by his *nom-de-plume* Dagonet, has this to say upon the above subject in his journal, the *London Referee:* "We hear a good deal of the tobacco habit and the alcohol habit, but very little notice has been taken of a habit which is more common than either, viz., the medicine habit—which prevails to quite an alarming extent. It affects all classes, and when once it gets a victim in its clutches it never lets him go. There are hundreds of thousands of Englishmen who take medicine of some sort every day of their lives. They do not, as a rule, trouble the doctors—they doctor themselves. They take pills and draughts, patent medicines, and old-fashioned remedies with as much regularity as they take their meals. The habit is not confined to the class that read the advertisements of wonderful cures, and take the various remedies one after the other, even when they have nothing the matter with them. Every chemist has upon his books well-to-do customers who have mixtures made up almost every day. A doctor is called in and gives a prescription, say for nervous depression or for dyspeptic trouble. That prescription will live for years. The entire family will try it one after the other, and get at last to take it about once a week as a mere matter of habit. The system having been saturated with medicine craves for medicine. The victims of the medicine habit would feel miserable if they were not dosing themselves. Some habitual medicine-takers, who have had a long illness and many prescriptions, will, when they get well, have the prescriptions made up again one after the other, and go through the whole series three or four times a year for the rest of their lives. There are families to whom the chemist sends in his book weekly just like the butcher or baker. Some of the customers are not content with one kind of medicine at a time. I know one man who frequently takes doses from four or five different bottles during the day, and who, when he goes out of town for a fortnight, takes his favorite mixture with him in quart bottles. He also has a packet of about fifty prescriptions in his portmanteau in case of accidents."

SOME CONSERVATIVE JOTTINGS APROPOS OF SPINAL ANÆSTHESIA.

BY J. LEONARD CORNING, A.M., M.D., LL.D.,

NEW YORK.

WHENEVER propositions tending to modify the trend of current practice are brought before the profession they incur a twofold danger: (1) either they are received with an indifference born of former and manifold disappointments; or (2) they excite anticipations beyond their legitimate potentiality. In the first instance, the proponent may be compelled to wait a long time for an audience; or, if his proposals be not vital with truth of that insistent character which will not down, he may never obtain a hearing.

The fate of spinal anæsthesia, however, is unique in this, that while at first and for long its advantages in a larger, and more especially in a surgical, sense were disregarded, there came a time when recognition leaped, as it were, into the arena of professional life, driving thence such small adjuncts of scepticism as remained. And from this long waiting and this belated acclamation has come a buoyant expectancy, a kind of vaulting zeal which sets one a-trembling at the possible consequences of disappointment, misapplication, or bungling. Spasmodic hardihood, defective technics, and so on to the killing! A thousand pities by a false thrust or impossible exactions to relegate once more to the limbo of the forgotten a procedure which, be the limits of its usefulness ever so sharply drawn, must still—in view of what has already gone before—possess a unique and extensive field of usefulness!

Though a neurologist, and strange to the great and useful art of surgery, I venture at this time to utter an unostentatious word of caution, trusting that by so doing I may serve a useful purpose, yet not offend.

In the issue of this journal for October 13, 1900, Dr. George F. Shrady thus expressed himself editorially:

"The value of recording original observations as soon as made and prospecting their adaptability to given ends is well shown in the matter of spinal cocainization, concerning which so much is being written and said.

"Although fully fifteen years have elapsed since Dr. J. Leonard Corning, of this city, published his experiments on this subject, and notwithstanding it is only within a few months that his suggestions have been followed, no one can question his claims to priority in first calling attention to a method of anæsthesia which is now challenging a trial by numerous surgeons here and abroad.

"As the real one who first established the principle of the action of cocaine upon the cord, and who first demonstrated its practicability not only by actual trials upon the lower animals, but by using it for anæsthetic purposes upon the human subject, his name must necessarily be associated with that particular field of work, however it may be extended by other investigators."

Here is gallantry; here chivalric treatment. But, as if this were not enough, and as though kindness, in prodigal mood, were determined to eclipse herself, he reveals at one stroke, in the last paragraph, thanks to a happy mating of insight with expression, the basic principle of my discovery of 1885,[1] as it has never been revealed before. Up to the time of my first publication in the *New York Medical Journal*, the fact that the cord could be brought under the dominion of an anæsthetic was utterly unknown. What I then accomplished was to prove that this could be done by injecting deeper and deeper between the vertebræ till I had produced all the phenomena of what I then called "spinal anæsthesia," or, as some prefer to call it, "medullary narcosis," precisely as they are produced by others to-day.

Time sped on, and I continued to experiment; till, perceiving with full force the utility of penetrating the meninges, the better to come at the cord, I began to produce anæsthesia of the cord by deliberately puncturing the membranes of the latter in the lumbar region, and depositing a cocaine solution directly upon the cauda equina.

A full account of these undertakings may be found in my book on "Pain"[2] (1894), and in the first volume of "A Reference-Book of Practical Therapeutics," edited by Frank P. Foster (1896).[3] Very recently Dr. L. Marcus has reviewed the historical side of spinal anæsthesia; and his paper, published in the MEDICAL RECORD for October 13, 1900, is a worthy contribution to the subject.

All my work in this field, be it remembered, was done and published years before any one else entered the field.

So much for recorded history, which confers beyond all challenge not only priority in principle, but priority in method as well. But to appreciate this fully it is, of course, necessary to read what I have written.

I have frequently been asked of late by numerous correspondents for an expression as to what, in my judgment, are the essentials of technique. To comply as succinctly as possible with these requests, the better to save much waste of ink, I would set down the following:

(1) The needle may be from three and a half to four inches in length. It should be fine, but not overtempered. The bevel of the point should be short, so that the needle will not require to penetrate the membranes very far, in order to insure the deposit of the solution within them.

The needle may be made of gold or platina, which metals being bendable are not liable to break, even when the calibre is small.

There should be a small steel nut, transfixed by the needle, sliding freely upon it, and fixable at any point of its (the needle's) length by the aid of a small set-screw.[4]

[1] The New York Medical Journal, October 31, 1885. See also the author's book on "Local Anæsthesia," D. Appleton & Co., 1886, p. 85.

[2] "Pain," J. B. Lippincott Company, Philadelphia, 1894, p. 247 *et seq.*

[3] D. Appleton & Co., 1896. See more particularly p. 281 *et seq.*

[4] This needle was described by the author in the MEDICAL RECORD of March 17, 1888.

When the needle is thrust in, and a few drops of the cerebro-spinal fluid emerge, this nut is slid down till its lower aspect rests upon the skin. The nut is then fixed in place by tightening the screw, and a further entrance of the needle into the spinal canal effectually prevented.

(2) A syringe of glass, graduated up to thirty minims or more, and provided with an asbestos packing, is the best because it is so easily and thoroughly sterilized.

(3) I prefer to employ a short, delicate trocar (see Fig. 1), half an inch in length, to penetrate the thick skin of the back, subsequently passing the needle through the opening of the trocar. This permits of the use of a very fine needle. Many of the needles recently employed by others are too large. The comparatively large puncture which they make in the membranes allows too much of the cerebro-spinal fluid impregnated with the anæsthetic to flow out, after withdrawal of the needle. Moreover, the bevel at the point of the needle is often far to long, necessitating, as has been said, too great a penetration beyond the membrane.

(4) As to the operator: He who undertakes to penetrate the membranes of the cord should go about it with clean hands: an application of soap and water, followed by washing with alcohol, and a dip in a solution of bichloride solution (1 : 2,000), will suffice to insure the necessary asepsis.

(5) As to the patient: The back should be scrubbed with (*a*) green soap and water; (*b*) bichloride solution 1 : 2,000; (*c*) ether; (*d*) alcohol.

(6) Sterilization of syringe: Cylinder, piston (withdrawn from cylinder), and needle should be boiled before use; and, thereafter, the hot water should be forced through the needle several times.

Fig. 1.

(7) The anæsthetic: At present cocaine (the hydrochlorate) gives the most satisfaction. A two-per-cent. solution seems to be the favorite, though I myself have tried many other strengths.

For the purpose of sterilization many are accustomed to boil the solution, which may be conveniently done in a test tube over an alcohol lamp. To facilitate the filling of the syringe, the solution may be poured into a watch-glass, previously well sterilized by boiling. Care should be taken to expel all air from the syringe before use. The solution should be allowed to cool before being injected.

(8) To make the injection: If possible the patient should be placed in a sitting posture, inclining in a forward direction, so as to bend the spine, and thereby cause some slight separation of the vertebræ.

I have made the injection at various points along the lumbar and even the lower dorsal spine. At present there seems to be in some quarters a predilection for the space between the spinous processes of the fourth and fifth lumbar vertebræ. It is, perhaps, a little easier to enter the canal at this point; but, whether the deposit of the solution higher up and nearer the cord proper is not better practice from a physiological point of view is, to my mind, still an open question. Certainly, to puncture, as I did years ago,[1] between the second and third lumbar vertebræ, would cause the anæsthetic to arrive at the cord more quickly and in a more concentrated condition than when introduced lower down. As a consequence, anæsthesia is more rapidly induced than when the injection is made lower down. If it be decided to inject at this point, the relatively profound depression between the first sacral and fifth lumbar may serve as a convenient landmark. Thence the spinous processes may be counted backward till the spine of the third lumbar vertebra is reached. This should be marked with India ink or a blue crayon. Just anterior to this point, and a little to the right of the ligament, the needle is introduced at something of an angle. I advise those who contemplate practising spinal anæsthesia to take a look at the skeleton, especially the relations of the lumbar vertebræ. An intelligent glance of that sort is worth many words.

The needle should be introduced slowly, the direction being slightly from without inward and from below upward. Any obstruction of its lumen may, of course, be cleared with the stylet. The outflow of a few drops of cerebro-spinal fluid will tell of the penetration of the membranes. The syringe may now be attached, and the injection made.

Even though the needle be small it should not be withdrawn immediately after the injection has been made; but on the contrary it should be maintained in place till the advent of anæsthesia. By so doing the opening made by the needle in the membranes is effectually plugged, and hence the anæsthetic cannot possibly flow out till it has done its work.

It is obvious from these considerations that plunging hither and yon and sawing with the needle are to be avoided. Better withdraw the needle and begin *de novo*, than risk the tearing of the membrane. The most recent physiology favors the close reciprocal relations between the cerebro-spinal fluid and the circulation of brain and cord. This is neither the time nor place to discuss the evidence bearing on the point. We shall do better to admit the contention, and accept the corollary that the spinal membranes should be injured as little as may be, and as small an amount of the cerebro-spinal fluid allowed to flow out as possible. Because the immediate effects of a considerable withdrawal of fluid are not necessarily threatening is no reason why we should wantonly modify the natural conditions.

When the heart's action is feeble or irregular, a small dose of strychnine, nitroglycerin, and digitalin may be exhibited hypodermically a short time before the cord is anæsthetized.

At present from ten to fifteen minims of a two-per-cent. solution of cocaine at a dose seem to give satisfaction. In the old days, however, when I first began experimenting, I was accustomed to inject very much larger quantities. But "enough is as good as a feast"; and it would be poor practice to add unnecessarily to the vehemence of the physiological effects.

Great stress has been laid by recent writers upon the outflow of the cerebro-spinal fluid as a criterion by which to determine with certainty that the membranes have been pierced. To admit the value of this sign, however, is one thing, and to declare that it is the only means of knowing that the membranes are pierced quite another. The latter assertion is incorrect. It is feasible by thrusting a needle down to the point of the spinous process to measure the distance between the latter and the surface of the skin. To this add the maximum length attained by the lumbar spinous process (in adults), say 4 cm., taking the measurement from the posterior wall of the canal. Then add a little (say ½ cm.) for certainty's sake, and to compensate for the slight inclination of the needle; thrust in and slowly inject a little of the anæsthestic and wait a few minutes. If after the lapse of ten minutes there is neither tingling nor numbness, go a little deeper and inject a little more. Often it is possible to obtain complete anæsthesia in this way.

[1] Referred to in my book on "Pain," J. B. Lippincott Company, Philadelphia, 1894.

A large amount of solution is, however, unnecessary to success, and I do not recommend it now, but cite it merely to show that there is more than one road to Mecca.

Again, and better, a needle may be thrust down to the transverse process—the upper (dorsal) surface of which corresponds approximately with the upper (dorsal) edge of the vertebral foramen—and thus the distance between the surface of the skin and the edge of the foramen may be quite accurately determined. Add half a centimetre to insure penetration of the membranes; set the nut accordingly on the hollow needle; insert, and inject gradually as before described.

Of course there is no objection, but on the contrary, good reason to watch for the appearance of the cerebro-spinal fluid at the top of the needle, which, if it does not absolutely guarantee the success of the anæsthesia, is certainly of the best omen.

A preliminary measurement of this kind is of especial service for purposes of orientation when the needle becomes filled with blood, and the cerebro-spinal fluid is not immediately forthcoming.

In 1888 I described this method of ascertaining the distance between the surface of the skin and the upper rim of the vertebral foramen, and designed a long needle with a handle to execute the manœuvre.[1]

All the world is now familiar with the phenomena induced by such injections: the paræsthesia—tingling, numbness, "sleepiness"; the subsequent disappearance of sensibility to pain in the regions below the point of injection, as well as the familiar constitutional symptoms of the drug.

I have minutely described these phenomena in my very first paper (1885),[2] as well as in subsequent writings; and what has been published recently in the course of what might be termed the late renaissance of my ideas serves but to confirm my own observations of long ago.

And now a further word or two as to the danger of expecting too much from this discovery, and of bringing it once more into the neglect certain to follow in the train of disappointed hopes.

First and foremost, it is necessary frankly to look at facts and confess that there is nothing in those till now brought forward remotely to warrant the belief that the days of cerebral or general anæsthesia are numbered. Some curtailment in their use there may, ay, doubtless will be; but abdication of their broad dominion—never.

Again, it is absolutely necessary to remember that, despite all apparent conformity with the exactions of technique, spinal anæsthesia sometimes leaves one in the lurch. To what is this failure to appear ascribable? Is it due to the outflow of the anæsthetic through the puncture, or to a lack of proper distribution? I do not know, nor have I yet come upon a convincing explanation. In such cases, after all has been done that ingenuity can suggest, resort to general anæsthesia is, of course, imperative.

Equally disappointing, or nearly so, are the cases in which the subject quite naturally suffers the imagination of pain rather than its reality. Failure to appreciate this fact may lead not only to disappointment, but to wholesale and unmerited condemnation. Cases are of record, too, in which the anæsthesia was not of sufficient duration, and the injections had to be repeated, always a deplorable circumstance. Future development of the technique may, however, render such supplementary injections either less inconvenient than they now are, or even altogether unnecessary. Just now experiments are being conducted with various anæsthetics, but cocaine still holds, and is likely to hold, the field. I know of no facts in physiological chemistry capable of explaining the discrepancy in the local effects of different anæsthetics, when used about the cord.

Often the anæsthesia, both in quality and duration, leaves absolutely nothing to be desired; and this without notable modification of technique or any other apparent departure. Such facts, it seems to me, should urge all concerned to studious attempts to solve the physiological riddle of this perfection, the better ultimately to attain constancy of result.

Uncouth needles, with a long bevel at the point, are of all things to be avoided. Only imperfect results are to be anticipated from such clumsy implements, as,

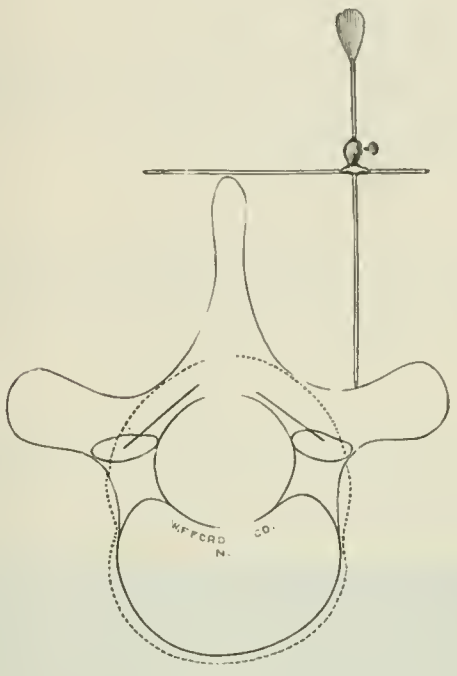

FIG. 2.

on the one hand, an overplus of penetration is requisite to insure the entry of the fluid below the membranes; and, on the other, an immoderate outflow of cerebro-spinal fluid—and hence of the anæsthetic—is inevitable after withdrawal of the needle.

The comparative value of injections made at different points along the dorsal and lumbar spine should also be carefully tested. I know very well that something has already been done in this direction, and I myself have had, in times past, a hand in such undertakings; but this phase of the question, simple though it may appear at first view, is, in my opinion, not yet conclusively decided.

Every one at all conversant with the serious results inevitably following infection of a serous cavity must be profoundly impressed with the necessity of a rigid asepsis. This point has been insisted upon by most if not all recent writers. Yet I foresee that amid the indiscriminate slitting by irresponsible persons, sure to follow in the wake of the conservative achievements of the judicious and the competent, there is likely to be a neglect of those necessary and elaborate rules of antisepsis so necessary to the safety of the subject. Then a procession of gory tales; and a great and useful principle cast into shadow by the misadventures of a herd of venturesome empirics.

There has, it is true, been a singular immunity from fatality till now—not a single death, I believe; but the history of innovation in the realm of anæsthesia does not countenance the hope that this can go on indefinitely. No; there will be fatalities, but let there

[1] The MEDICAL RECORD, March 17, 1888.

[2] The New York Medical Journal, October 31, 1885.

be a concerted effort by the invocation of every known precaution to keep the percentage of mortality as low as possible. Let there be less rivalry of the knife—less endeavor of one to outslit the other—and more attention to improvement of method by the invocation of the good offices of experimentation and the creative imagination.

Again, I repeat, I am no surgeon; but, as a neurologist, I tremble for the cord. In view of such solicitude, may I be forgiven this preachment—the only bit of strenuous didacticism, so far as I can recollect, of which I have been guilty during my entire professional career.

Finally, the author desires to express his sincere acknowledgment of all the kind things which have been said of the method, both by his confrères and the medical press. It would, however, be a sorry misinterpretation of its significance were the author to regard all this eulogy as a personal compliment. On the contrary, he is fully aware that the applause is for the idea as a part of the heritage of American medicine, and not for himself.

53 West Thirty-eighth Street.

THE TREATMENT OF NECROSIS OF THE ENTIRE SHAFT OF A LONG BONE; WITH REPORT OF A CASE.

By J. SHELTON HORSLEY, M.D.,

El Paso, Texas.

Acute osteo-myelitis is responsible for the largest portion of the diseases of the shafts of long bones, so its importance to the surgeon can hardly be overrated. It usually follows a definite and typical pathological

Fig. 1.—The Patient after Operation.

course, though the symptoms are not so well defined, especially in the early stages, when the diagnosis is frequently confounded with that of rheumatism or typhoid fever. It is practically only for necrosis as a sequela of this disease that shafts of long bones have to be removed subperiosteally, for after severe injuries the periosteum is destroyed with the bone, and in malignant diseases it is involved.

The time required for separation of dead bone may be from four weeks to a number of months. Living bone immediately adjacent to necrosed bone undergoes rarefying osteitis, softens, and becomes gradually converted into granulation tissue. Suppuration occurs where the dead and living bone are in contact. New bone is being constantly formed from the periosteum and from the granulations which have separated the sequestrum; and this new formation, constituting the involucrum, is necessarily thoroughly infected with pus organisms, as it is constantly bathed in pus during ossification.

But however definite the pathological course that leads to necrosis of shafts of bones may be, the process of repair after operation is not so well defined. Occasionally bone will not be reproduced either from whatever remaining bone there may be left or from the periosteum. In March, 1899, I saw in consultation with Dr. J. F. McConnell, of Las Cruces, N. M., a middle-aged man of excellent physique and good general health, who had had a circumscribed area of necrosed bone in the upper epiphysis and adjacent portion of the shaft of the tibia. This had been thoroughly removed, and a few weeks later the walls of the resulting cavity were curetted. The wound followed an aseptic course as a result of these operations, yet with the exception of a few isolated patches of insignificant granulations there was, during the course of more than six months, no attempt at reproduction of bone; and this in spite of the fact that decalcified bone chips and numerous other measures had been patiently tried. The man finally committed suicide, rather than lose his leg.

Every surgeon of much experience in emergency surgery has had at least one case of ununited fracture that would unite by no known method of treatment. This frequently occurs in young or middle-aged patients who have had excellent health and are without a trace of constitutional or hereditary disease. Age modifies reproduction of bone. It is a well-recognized fact that in the young bone is reproduced much more rapidly than in the old. Swoboda,[1] after a study of osteomyelitis in infancy, finds it more acute and necrosis of bone more rapid than in adults. Epiphyseal separation, he says, is also more likely to occur. Reproduction of bone in infancy unquestionably requires a shorter time.

When we consider that bone and periosteum are abundantly supplied with blood, and that they belong to the connective-tissue group, a comparatively low grade of tissue histologically, we cannot help wondering why reproduction of bone is so uncertain and irregular. Wounds in much more highly constructed tissues, except in central nerve matter, are almost invariably repaired more or less perfectly. Yet with comparative frequency we find injuries of bones—a pure connective tissue—followed by no attempt at repair, even after the most careful and skilful treatment.

So in a small proportion of cases failure will result, but in the vast majority of instances the periosteum alone is fully capable of reproducing the entire shaft of a long bone when reproduction is at all possible. Dr. H. W. Cushing, of Boston, reports a case[2] in which the entire shaft of the tibia was removed, and another regenerated from the periosteum. He attributes the successful result largely to the time at which the operation was performed, when the periosteal osteoblasts were in the most active regenerative stage, but before an involucrum had formed. An in-

[1] Wien. klin. Woch., vol. x., 1897.
[2] Annals of Surgery, October, 1899.

volucrum always contains pyogenic germs that may live in its small foramina and crevices almost indefinitely. For this reason and on account of the denseness of bony structure, it is wellnigh impossible to disinfect it.

In necrosis of the entire shaft of long bones, not only the sequestrum but the involucrum should be completely removed, the periosteum being carefully preserved. After removal of a sequestrum, the involucrum consists of a mass of badly formed bone, impossible of being rendered aseptic, and containing a cavity which, under the most favorable circumstances, is difficult of closure. If the periosteum is carefully stripped off, the wound can be treated as in

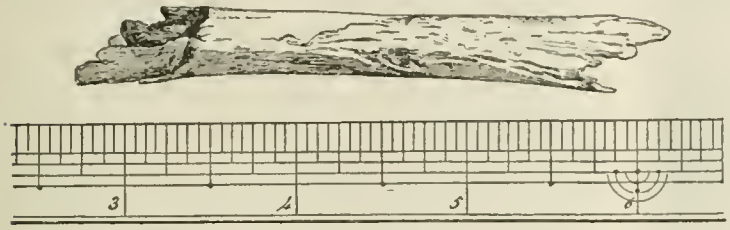

FIG. 2.—The Sequestrum Removed.

the case of Cushing by sutures, leaving buried in the leg "a solid cord of bone-producing tissue," or if the periosteum itself is infected, may be lightly packed with gauze, as in the case here reported. In either event, the reproduced shaft will more nearly correspond in both shape and quality to the natural diaphysis than is possible than by leaving a clumsy, infected involucrum surrounding a large dead space. The following case of necrosis of the entire shaft of the tibia serves to support this view:

B. E——, girl, aged one year and eight months; German-American parentage; has three brothers, all healthy. Family history of no importance. About September 1, 1898, she commenced suffering from pain and some swelling in both legs. The right leg recovered, but the left grew worse, and finally an abscess formed near the upper end of the shaft of the tibia. This was opened by Dr. J. F. McConnell, who found a movable mass of dead bone at the bottom of the abscess. On October 30, 1898, he referred the case to me for operation, with a diagnosis of necrosis of the shaft of the tibia. On the following day I operated, with his assistance. A long incision, the length of the shaft of the tibia, was made over its interior surface near the anterior border. Attempts at involucrum formation at the upper third of the shaft were poor, and resulted in only a few bony spicules, but in the lower and middle thirds a thin layer of soft, cheesy bone had formed. After the periosteum was raised, the front of this was removed, and a sequestrum exposed. All of the remaining involucrum seemed infected, so it was removed with a sharp spoon and periosteal elevator, leaving at the lower part of the leg a small strip that was closely united to the lower epiphysis and apparently healthy. The upper epiphysis was badly infected, but a Volkmann spoon thoroughly removed its diseased bone. The upper part of the periosteum was gently scraped, and the wound lightly packed with iodoform gauze. It was dressed every third day. Recovery progressed slowly but satisfactorily. Two small sinuses existed near the upper end of the incision for ten months, but finally closed. The leg is now useful, and a slight bowing of the tibia seems not to interfere with its function. The photographs showing the leg were taken in June, 1900, twenty months after the operation.

Supra-Orbital Neuralgia.—Castor oil two or three times a week, to be kept up at less frequent intervals after pain ceases.—N. O'D. PARKS.

TREATMENT OF THE PATIENT DURING THE WEEKS PREVIOUS TO EXPECTED CONFINEMENT.

BY EDWARD P. DAVIS, A.M., M.D.,

PROFESSOR OF OBSTETRICS IN THE JEFFERSON MEDICAL COLLEGE; PROFESSOR OF OBSTETRICS AND DISEASES OF INFANCY IN THE PHILADELPHIA POLYCLINIC; VISITING OBSTETRICIAN TO THE JEFFERSON, PHILADELPHIA AND POLYCLINIC HOSPITALS, ETC.

WE shall best understand the treatment needed by the pregnant woman during the later weeks of gestation by reference to the condition of the patient during this time.

If she be healthy, the mother's nutritive processes are well performed. The anæmia of early pregnancy has given place to the plethora of its later stages. The patient's excretion is often better than at seven or eight months. In those who are overtaxed, ill-nourished, and living in unfavorable surroundings, the later weeks of pregnancy find them with a threatened toxæmia which may lead to eclampsia. In neurotic women and those who habitually excrete badly, it is also true that the later weeks of pregnancy form a period of increasing danger.

In women of normal shape and tissues, the pelvis undergoes changes during the later weeks of pregnancy which fit it to give passage to the child. Its joints become more filled with synovial fluid, and its articulations more elastic and capable of distention. This is an important factor in securing that accommodation so essential to the normal mechanism of labor. Uterine contractions become more pronounced at this time, and, aided by the action of the abdominal muscles, cause the entrance of the fœtus into the brim of the pelvis in primiparæ and its presentation at the pelvic brim in multiparæ. Observation shows that a very important function in securing accommodation is that of the voluntary muscles, as seen in cases in which pregnant women in the later months of pregnancy take exercise and thus assist in causing the child to descend.

Mammary changes during the later weeks of pregnancy prepare the breasts for nursing by the accumulation of colostrum, and warn us to see to it that the nipples are brought into condition for this function.

To estimate the perfection of the patient's assimilation and to detect failure in excretion, we must study the clinical symptoms of toxæmia, and by examination ascertain chemically, so far as possible, the condition of the excretory processes. Attention has long been drawn to the violent frontal headache, lassitude, disturbance of vision, and high pulse tension which often precede eclampsia. There are other symptoms, however, which mark the pre-eclamptic state and whose recognition is of importance. The persistent presence of gas in the intestines, with a furred and coated tongue, points to deficient elimination. Neuralgia, disturbance in the rhythm and frequency of the heart beat, changes in temperament, slowly progressing loss of appetite, deficient action of the skin with, in many cases, eruptions, vague headache frontal in character but not extremely severe, failing excretion by the kidneys, liver, and bowels, form a clinical picture not difficult to recognize if the attention be directed to it. In rare cases uterine hemorrhage is a most important symptom of profound toxæmia.

In examining the urine, we ascertain its quantity, its amount of solid material, and the presence or absence of débris from the kidney as of primary importance. Of secondary value is the presence or absence of serum albumin and of lactose.

To ascertain the solid waste, the specific gravity of the urine should be taken, and the last two figures of this number multiplied by 2.33 give approximately

the number of grams of solid matter in one thousand cubic centimetres of urine. Haines' modification of Haeser's method consists in multiplying the last two figures of the specific gravity by the number of ounces voided in twenty-four hours and the product by 1.1.

The estimation of the amount of urea is valuable not only to assist us in measuring the quantity of solid matter excreted, but also because the presence of urea in considerable amount indicates that assimilation is well performed and that nitrogenous food is well digested and is not broken up into irritating and poisonous compounds. Hence the estimation of urea during pregnancy is an important clinical resource, the value of which experience has fully confirmed. A number of convenient forms of apparatus are readily available for this purpose.

It is sometimes difficult in dealing with patients to induce them to measure accurately the quantity of urine passed and to send specimens regularly for examination. In most cases, however, the patient cooperates willingly in the physician's attempt to give her accurate care. Kidney débris may be obtained by the use of the centrifuge or by sedimentation. The character of the epithelia, the degree of degeneration present, the number and character of casts found, and the presence or absence of blood give reliable information as to the condition of the kidney.

Serum albumin when present in excess is accompanied by kidney débris and indicates a seriously impaired condition of the renal epithelium. Unless, however, kidney débris is present and the solid waste is poorly eliminated, serum albumin alone is of little significance as an indication of danger. Anæmic multiparæ are sometimes seen with much swollen legs, who have considerable quantities of serum albumin in the urine but who excrete well in other ways and pass through pregnancy without danger.

The presence of various forms of sugar in the urine suggests interesting problems. Lactose is naturally referred to the activity of the mammary glands. Other forms of sugar may be seen in highly nervous women who have ravenous appetites and eat very largely. In a case now under observation, at the fourth month of pregnancy, a highly nervous multipara had for some time in the urine an average of one per cent. of sugar which was not lactose. This was accompanied by polyuria and excessive appetite. Sugar is now absent from the urine without especial modification of the diet or medical treatment.

The treatment of the toxæmia of pregnancy is too large a subject to occupy us extensively at this time. Experience constantly proves that physicians must not be deceived by supposing that serum albumin is the most important indication of failing excretion. The part which the liver plays in the production of poisonous compounds causing eclampsia is recognized more and more. The physician must satisfy himself that the liver, intestines, kidneys, skin, and lungs are doing their part in digestion and excretion.

The diet of the patient should be as nearly as possible milk, fruit, and bread. If heartburn be annoying, milk may be diluted with any carbonated water with advantage. In some cases it should be partially peptonized. Buttermilk is exceedingly useful with those who can take it. In my experience the majority of women in comfortable circumstances can limit the consumption of meat during the latter two-thirds of pregnancy to once daily with advantage. Fish, oysters, white meat of poultry, and mutton or lamb are to be preferred when meat is taken. The alkaloids of tea and coffee check excretion very markedly with some women. Coffee is especially injurious to those who suffer from chronic intestinal indigestion. Alcohol in toxæmia is not indicated but injurious. The mistake must not be made in dealing with these patients so to limit the diet as to reduce strength. It often requires considerable perseverance and attention to induce the patient to take sufficient milk. The skilful preparation of milk foods such as junket, koumiss, and milk puddings is of great assistance. When thoroughly ripe fruit is not available, fruit should be stewed or baked, and when fresh fruit cannot be obtained, dried fruits and those put up with little sugar should be used.

The use of water in toxæmia deserves especial mention. At least one quart should be taken internally daily, and this may be any pure water agreeable to the patient. Externally, water should be used in a cool sponge bath in the morning and a warm tub bath at night. The evening bath is our best reliance in diminishing the irritability and insomnia which often annoy these patients. Water may also be used in flushing the colon and by injection into the bowel. In cases of obstinate constipation when the bowel has been emptied, a daily flushing with one gallon of decinormal salt solution followed by the injection of two quarts of sterile water is of great advantage. A skilful nurse can usually succeed in this treatment by turning the patient on her left side with her hips raised and by introducing a long rectal tube with patience and gentleness.

The patient must spend as much of the day as possible in the open air, and her house must at all times be well aired.

The choice of drugs in the treatment of toxæmia is in my experience a limited one. Salines should be selected for their freedom from potassium. Sulphate of magnesium in some form is especially valuable. Carlsbad salts taken in hot water upon rising answer exceedingly well in many cases. In others, a mineral water, rich in sulphate of magnesium, may be selected. Those patients who are annoyed by the presence of gas often complain that salines increase the gas in the intestine, and this statement is borne out by careful observation.

I know of no drug which so efficiently influences the throwing out of solid waste in the body as calomel. In doses of $\frac{1}{20}$ of a grain night and morning or in much smaller doses, $\frac{1}{100}$ of a grain three times daily, in my experience it is most successful. I have continued this for several weeks without signs of mercurial irritation. It is sometimes necessary to supplement this by salines, while others do well upon this drug only. Under its use the percentage of solids in the urine increases, the percentage of urea is distinctly increased, the pulse tension is lessened, the patient's symptoms are much improved, and her condition is very greatly benefited. I know of no other drug which is of essential value in this condition. If the patient complains of insomnia, restlessness, and headache, the practitioner would natually be tempted to give sedatives, notably bromides. This in my experience is a mistake, as treatment addressed to increasing elimination causes the disturbance of the nervous system speedily to cease. If a sedative is needed in toxæmia, chloral or some derivative of it, gives the best promise of success.

Up to the present time, I have been uniformly successful in the treatment of toxæmia during pregnancy by the methods described. An illustrative case is the following: The patient was in her sixth pregnancy. The first was followed by a miscarriage upon violent exertion. During the second, she was exposed while yachting to severe cold, followed by a sharp attack of nephritis, from which she was rescued with difficulty. Her next pregnancy was followed by an abortion at six months. In the next pregnancy at eight months, albuminuria developed rapidly and labor was induced with the birth of a living child which survives. At the next pregnancy, she had

eclampsia and labor was induced, followed by the birth of a child which soon died. She came under observation when one month pregnant for the sixth time. The patient was in other respects strong and robust and had in previous pregnancies strictly followed the general hygienic precautions which her physicians had ordered. Her case had been very carefully and thoroughly studied during previous pregnancies. The examination of her urine showed it to be normal. Owing to the bad previous history, pregnancy was considered most hazardous by the physicians consulted in the case. When seven weeks of pregnancy had elapsed, hyaline and granular casts with a trace of albumin were found in the urine. The amount of solids excreted continued good. The interruption of pregnancy was declined by the patient, who preferred to make a further effort to secure a second living child. Accordingly between the tenth and twelfth week of gestation the patient was put upon a diet from which meat was omitted and nitrogenous food reduced very largely. Examinations of the urine were made most carefully each week, and the patient was seen frequently by her attending physician. The only medication employed was calomel in $\frac{1}{20}$-grain doses and a saline taken in the morning. The patient gave up her entire life to the continuation of the pregnancy, and in addition to restriction of diet and medication, followed strictly other precautions in maintaining her general hygiene. She was warned that in the later months of pregnancy labor might come on rapidly, and as pregnancy progressed and elimination began to decrease, her urine was examined daily. At about eight months, she suddenly expelled a living child weighing five pounds fourteen ounces. This child survives in excellent condition and is still nursed by its mother. Both have made an excellent recovery. The placenta in this case was highly degenerated, a large portion being filled with white infarcts. In this case, the fact that the husband is a physician and that she was so closely watched made the continuance of pregnancy possible. Every preparation was made to empty the uterus should the patient fail at any time during the pregnancy. In view of the fact that she had taken most careful precautions regarding diet and in other ways during previous pregnancies which had resulted disastrously, the success of the last pregnancy may be thought to be owing not only to general precautions but to the use of calomel under the observation of her husband, at intervals during the later months.

While the descent of the fœtus into the pelvic brim is a spontaneous process, it may be aided by the voluntary acts of the mother. Such exercise as causes the muscles of the lower extremities and of the abdominal region to contract while the patient is erect or bending forward is most efficient in furthering the descent of the fœtus. To utilize the muscles of the upper portion of the body, the patient must contract them while in the kneeling or squatting posture. Scrubbing a floor or stairs while kneeling is most efficient. Such exercise, however, is not available among those well to do. Walking is also useful and is the most available exercise for all classes of patients.

The arrangement of the patient's clothing is not without influence in furthering or hindering the accommodation of the fœtus. It is possible by extreme compression of the abdomen to force the child down upon the pelvic floor, as seen in cases of illegitimate pregnancy, in which the mother laces tightly to hide her condition. Long-continued compression, however, so weakens the abdominal muscles that accommodation is imperfectly secured in spite of the downward pressure exerted. To bring about the desired result, the patient should be advised to remove all constriction from the abdomen, to allow the uterus to assume as nearly as possible its natural situation. The bowels should be kept open and the patient urged to take exercise. Should the abdomen be pendulous and the uterine wall stretched, it may be necessary to apply a well-fitting abdominal supporter or bandage.

The presence or absence of accommodation is to be ascertained by palpation and the comparative test of fitting the child's head into the pelvic brim. If the head has entered the brim, this will be detected by grasping the head between the thumb and fingers of one hand placed above the pubes or by grasping the head with the two hands pressing deeply into the tissues parallel to Poupart's ligaments upon each side. A vaginal examination will confirm the diagnosis, and inform us of the degree of descent present. Attention must be called to the fact that the child's head may lodge at the brim of the pelvis, and strong lateral flexion taking place, may force down one of the parietal bones, giving a very deceptive impression to the finger of the examiner. Mistaking the parietal eminence for the vertex, he may imagine that descent has begun when the head has not entered the pelvic brim. In cases in which the induction of labor must be accepted or rejected, if there be difficulty in making an examination, an anæsthetic should be employed. In patients who take ether badly, chloroform may be used with great comfort to the patient and convenience to the physician. With anæsthesia, the physician can make a bimanual examination of the position of the head, fitting it into the pelvis with one hand while the fingers of the other study its position and relation to the pelvic brim. It must not be forgotten that success in such an examination requires that the bladder be empty, and that it is well to catheterize a patient who is under an anæsthetic, because the nervous apprehension of anæsthesia often results in a free, sudden secretion of urine, thus distending the bladder with but little warning. Aseptic precautions should be observed in this as in all other manipulations during pregnancy.

For disproportion and disease threatening life, the induction of labor is clearly indicated.

I can allude but briefly to the most recent papers upon the induction of labor and its results. Heymann[1] reports one hundred and seven cases of induced labor. For disproportion he chose the thirty-third or thirty-fifth week of gestation; 64.3 per cent. of the children survived. The shortest antero-posterior diameter of the pelvic brim in his cases was 7 cm. He could trace no mortality among the mothers which he could fairly assign to the induction of labor. He failed in some cases to rescue the mother from a dangerous condition by induced labor. Aside from disproportion, he induced labor most frequently for threatened eclampsia, lesions of the heart, and tuberculosis. His method was that of Krause: the introduction of an aseptic bougie to excite uterine contractions. In Schauta's "Festschrift"[2] Skorscheban reports forty-four cases of induced labor, eleven of them for contracted pelvis. He chose the thirty-fourth to the thirty-eighth week and secured 91.7 per cent. of living children. There was a large mortality among these children during the first year of life. The mothers had no mortality traceable to the operation. In thirty-three patients he induced labor three times for osteomalacia, in fourteen for lesions of the heart, in seven for nephritis, in three for pernicious nausea, in five for tuberculosis, and in one for paratyphlitic abscess. The mortality was six per cent. among the mothers; 79.4 per cent. of the children were born living. The success of induced labor is emphasized by Grusdew's

[1] Archiv für Gynäkologie, Band 59, Heft 2, 1899.

[2] Monatsschrift für Geburtshülfe und Gynäkologie, Band 11, Heft 1, 1900.

report.[1] He terminated pregnancy in this way nine times in one patient. A new method of inducing labor is advocated by Spinelli.[2] He carries a strand of gauze soaked in ichthyol and glycerin between the membranes and the wall of the uterus. A plea for the revival of Kiwisch's method of inducing labor by vaginal douches is made by Sarwey.[3]

Disorders of the blood during pregnancy become most pronounced in the later months and demand recognition and treatment. An examination of the blood will reveal the nature of the disease and give us valuable information as to the severity of the process. If leucocytosis is well marked, we may suspect some chronic inflammatory process with the development of a focus in the pelvis, which may occasion septic infection after confinement. If the patient is highly anæmic and the corpuscles are much disintegrated the danger of hemorrhage during and after labor will be considerable. In the treatment of these conditions, the action of the intestine must be stimulated by gentle but thorough purgation, and arsenic, iron, and bitter tonics employed liberally. The abundant use of milk is especially valuable with these patients.

One of the causes of anæmia in pregnancy is syphilis, and search must be made for this disorder in all highly anæmic patients. The treatment of syphilis during pregnancy must be not only constitutional but local, and thorough disinfection with green soap, mercurial solutions, and lysol or carbolic acid is demanded. The danger of septic infection following labor in syphilitic women having an active lesion in the vagina or cervix is so great that heroic measures may be justified during pregnancy. The use of strong antiseptic mixtures, such as carbolic acid and iodine upon these lesions, or even the application of the cautery may be demanded.

In the later months of pregnancy, infection by gonorrhœa must receive attention. The free use of douches of tincture of green soap and water, followed by bichloride injections, gives good results. The region of the urethra and meatus must be thoroughly cleansed and disinfected by suitable measures.

Cancer in the later months of pregnancy may increase with distressing rapidity, causing hemorrhage and threatening the life of the patient. If the cervix be extensively diseased, it is better to extract the child by Cæsarean operation, removing the entire womb.

The possibility of autogenetic infection is of great interest in connection with the responsibility of the physician to prevent sepsis by the disinfection of the patient before labor. At the recent Paris Congress, Doléris, Menge and Krönig, and Pestalozza read papers upon this subject, distinctly reiterating the belief which has been held by many, that previous infections may leave a patient during her pregnancy with infectious germs within the birth canal. While in perfectly healthy women the birth canal is aseptic and its secretion antiseptic, if this canal has been invaded by gonorrhœa, syphilis, cancer, or other mixed infection, in pregnancy subsequent to this infection the patient must be considered as capable of autogenetic sepsis. It is the duty of the physician in the later months of pregnancy to know whether his patient has a vaginal discharge indicative of infection. If possible, a bacteriological examination of suspicious discharges should be made, and such disinfection practised as the results of the examination indicate. Certainly no obstetrician could be held entirely responsible for puerperal septic infection in the case of a patient who at the time of labor was known to be suffering from a pre-existing infection. So difficult is it to thoroughly disinfect the birth canal that our efforts to do so are not always attended by success. That this effort must be made is evident, but we must also remember in such cases so to conduct labor as to give the least opportunity for infection, and we must recognize the danger of infecting others from such a case.

During the later weeks of pregnancy the drawing out of the nipples, the cleansing of their surfaces, and the healing of cracks and fissures in the epithelia should receive attention. Sterile cocoa butter or olive oil, subnitrate of bismuth and castor oil, and a borated lanolin or oxide-of-zinc ointment are all useful. Congenital fissures of the nipple expose the patient to added danger, because the epithelium is often thinner than usual upon these surfaces.

Abnormal conditions of the fœtus may often be diagnosticated during the later weeks of pregnancy and demand attention. The coiling of the cord about the child's neck may be recognized by the murmur which accompanies it, and warns the obstetrician not to permit the labor to continue indefinitely lest pressure upon the cord and asphyxia should result. Abnormal presentations may often be corrected in the very first stage of labor and threatened danger avoided. Polyhydramnios may require the rupture of the membranes at the later portion of the first stage, with compression of the abdomen and uterus in the interests of mother and child. Rapidly increasing polyhydramnios calls for the interruption of pregnancy, and the patient must be warned that sudden rupture of the membranes may occur at any time.

During the later weeks of pregnancy occur those hemorrhages from partial separation of the placenta which are so dangerous to mother and child. In cases in which direct violence is present as a cause, the accident is sufficient to warn the obstetrician. An abnormal position of the placenta can often be detected by auscultation and palpation, and thus the physician can be warned of the danger of hemorrhage at the very beginning of labor. The presence of a serious heart lesion in the patient, of advanced kidney disease, and of any condition interfering seriously with the circulation of the blood through the abdominal viscera, predisposes to hemorrhage in the later months of pregnancy. The detection of this condition must put the obstetrician upon his guard.

By placenta prævia we understand such an attachment of the placenta that it is separated from the uterus when dilatation of the womb begins. If the placenta be as low in the womb as the lower uterine segment, it is, properly speaking, a placenta prævia. It is not infrequently possible to diagnosticate such an attachment if the placenta be upon the anterior wall of the uterus. The recent papers of Ponfick[1] and Fraenkel[2] describe recent investigations into the anatomy of placenta prævia which illustrate the point in question. In the treatment of this condition the diagnosis of central placenta prævia at any time during pregnancy must be followed by the immediate termination of the pregnancy. This may be done by the gauze tampon or the elastic bag as recommended by Von Holst[3] in a recent paper. If the patient be near term and the child viable, if the conditions for operation are favorable, some urge delivery by Cæsarean section. Experience in this application of the Cæsarean operation is not yet sufficient to warrant a positive recommendation. The treatment of placenta prævia by rapid dilatation and version is not without danger as illustrated by Schutze's case,[4] in which rupture of the uterus followed delivery in placenta prævia by

rapid dilatation and version. The use of elastic bags may lead to accident as in Jardine's case.[1] In inducing labor for contracted pelvis and placenta prævia, a De Ribes bag was introduced as a dilator. The bag burst and the fluid which it contained rapidly separated the placenta, causing sudden and severe hemorrhage.

The later weeks of pregnancy give opportunity for a most useful study of the pregnant patient, by which the possibilities for spontaneous labor may be ascertained, abnormalities detected, complications foreseen, and such measures taken as to conduct the woman and her child safely through the perils of parturition. A physician loses a great opportunity not only to enhance the welfare of his patient, but to increase his own knowledge and skill if he neglects this period of gestation.

SOME APPLICATIONS OF STATIC ELECTRICITY IN DERMATOLOGY.[2]

By HENRY G. PIFFARD, M.D., LL.D.,

NEW YORK,

PROFESSOR (EMERITUS) OF DERMATOLOGY, NEW YORK UNIVERSITY.

Static electricity as a therapeutic aid was first employed in America by Benjamin Franklin, about one hundred and fifty years ago. He placed patients on an insulated stool, charged them from a simple frictional machine, and drew sparks from various parts of the body. He also charged large Leyden jars, and discharged them through the patient. With this technic he benefited temporarily or permanently a few cases of paralysis. Others, both in America and abroad, employed static electricity to a limited degree, extending somewhat its range of application.

The voltaic cell, however, came into notice as a therapeutic agent and gained many adherents, in consequence of the simplicity of its operation, and static electricity was relegated to the background. The earlier types of cell—zinc-platinum (Grove) and zinc-carbon (Bunsen), both employing porous cups and strong acids—were inconvenient, insomuch as it was necessary to dismantle and clean them immediately after use. The Smee (zinc-platinized silver) and the Grenet (zinc-carbon), each requiring but a single fluid, rapidly displaced the Grove and Bunsen types, and shared the popularity accorded the Daniel cell and its modifications. An efficient apparatus, however, adapted to general use, required a battery of from twenty to forty cells, capable of generating a current of from twenty to eighty volts, according to the type of cell employed. The current from such a battery flows continuously in one direction.

The studies of Faraday later led to the introduction of a new type of electrical apparatus which is frequently called after his name. This consisted essentially of one or more voltaic cells, a soft iron core and hammer, and two concentric coils of copper wire, insulated from each other; the outer coil having a longer and finer wire than the inner. The circuit from the cells traversed the inner coil, and being broken by the interrupter, generated or induced a current of higher voltage in the outer coil. Instead of using voltaic cells to generate the primary current, the constant direct current from a dynamo may be conveniently employed as I have formerly shown (*New York Medical Journal*, July 11, 1891). Instead of the magnetic interrupter, the initial current may be broken by some mechanical device, as a toothed wheel revolved at a rapid rate by an electro-motor. If Leyden jars or preferably flat condensers be added to the installation and properly connected up as in the Ruhmkorff, a current of still higher tension is obtained. If again, instead of the apparatus being actuated as above, the initial current be taken from a dynamo giving an alternating current, the magnet, and hammer, and the toothed wheel may be dispensed with, and the apparatus be both simplified and rendered more energetic. Some ten years ago Tesla developed this phase to a higher degree than any of his predecessors. In other words, he produced an apparatus that yielded a current characterized by an exceedingly high frequency of alternation, and of a voltage or tension that was a surprise to the world. Concerning the current he wrote as follows: "We operate a coil either from a specially constructed alternator capable of giving many thousands of reversals of current per second; or by disruptively discharging a condenser through the primary, we set up a vibration in the secondary circuit of a frequency of many hundred thousand or millions per second, if we so desire; and in using either of these means we enter a field as yet unexplored."[1]

This field has now been quite thoroughly explored from a physiological and therapeutic standpoint by d'Arsonval, Apostoli, and others. Briefly the effects of this H. F. (high frequency) and H. P. (high potential) current on the human system are an increased utilization of oxygen, an increased elimination of carbonic acid, and an increase in the general metabolism. In other words, it acts as a tonic, or, as I would prefer to term it, an energizer. This statement has been borne out by both clinical experience and scientific experiment. The local effects of this current I shall not allude to here, as those who are sufficiently interested can delve into the ample literature of the subject.

The distinguishing features of the Tesla current are the extreme rapidity of the reversals or oscillations of the current, so great indeed as to defy measurement and almost to defy computation, and accompanying the high frequency the potential is raised to a point and that seems incredible. This type of current, however, was already known to the world through the labors of Dr. William J. Morton, who first drew attention to the "static induced" current in various affections, and thus established a new era in electro-static therapeutics.[2]

Some have endeavored to detract from the credit due Morton in respect to the use of this current, claiming that generations ago its existence had been demonstrated. Be that as it may, it was certainly Morton who first used it systematically in the treatment of disease, and made public the fruits of his experience. Thousands of people had seen steam issuing from the spout of the tea-kettle, but the world waited for a Watts to harness this powerful agency and adapt it to so many useful purposes.

The physiological effects of the ordinary "faradic machine" consist in little more than localized muscular contractions, accompanied with more or less pain, but so far as I have been able to observe, the current possesses but little constitutional influence.[3] With the static induced current, on the other hand, one may obtain simultaneous tetanization of a large number of muscles with little or no pain, and constitutional effects similar to those obtained with the H. F. and H. P. currents derived from the D'Arsonval apparatus.

Static electricity and high-frequency currents have for some time been successfully employed in the treatment of certain cutaneous affections, more perhaps in

[1] "Experiments with Alternating Currents of High Potential and High Frequency," New York, 1892.

[2] MEDICAL RECORD, April 2, 1881.

[3] I am not unmindful of the claims made in behalf of Beard's "general faradization."

Europe than in America; and I am enabled by personal experience to corroborate in great measure the claims that have been made in their behalf.

Desiring to use in dermatologic practice high-frequency currents of even higher potential than those of the static induced current, my thoughts turned to the use of the Tesla oscillator, which would involve the installation of an alternating dynamo, condensers, and an up-step transformer. Tesla, however, states, as already quoted, that his H. F. and H. P. currents may be obtained by "disruptively discharging a condenser through the primary of a coil." All that would be necessary, therefore, would be to connect the coarse inner wire of a suitable coil in series with the static induced current.

Mentioning my requirements to Dr. Harry F. Waite, of this city, he constructed an up-step transformer that has yielded the most satisfactory results. The transformer itself consists of an inner coarse wire, the terminals of which are connected to the outer coatings of the Leyden jars of a large static machine. A long coil of fine wire surrounds the inner coil, and the whole is very thoroughly insulated by a modification of the Tesla insulation. The outer case measures seven by seven by twelve and one-half inches. From one side project the terminals of the primary, and from each end the terminals of the secondary coil. The Leyden jars are twelve inches in height and four in diameter, and the inner and outer coatings extend to within two inches of the top. If the static machine be now brought into action, with the sliding poles separated so as to give a spark gap of two or three inches, electric streams issue from the terminals of the secondary coil. If the hand be brought to within about two inches of either terminal, a spark appears to leap forth and pierce the skin. The impact, however, is absolutely painless, in fact barely perceptible to the senses, in this respect quite unlike other static sparks. If fifty or a hundred of these sparks be directed to one point, the skin becomes slightly reddened, and the blush remains for several hours or even a day or two. The same phenomena appear whichever terminal is approached. If one terminal is grasped firmly with the hand there are absolutely no sensation and no muscular contraction, and the same is true even if both poles be grasped, one in either hand. It would seem almost beyond belief that an alternating current, with its millions of oscillations per second and its immeasurable voltage, also (by calculation) in the millions, should thus traverse the body without affecting it to a degree appreciable to the senses. Yet such is the case. Whether this current produces any physiological, constitutional, or metabolic effects, I have not determined, as my observations thus far have been confined to a study of its local effects on cutaneous lesions.

The most convenient way of applying the current is by means of special electrodes. One of these is a metallic point with insulated handle, and the other a closed glass tube about five inches long and three-fourths of an inch in diameter, with an inner coating of tin foil. This also has a long, well-insulated handle. The electrodes should be connected to the terminal of the secondary coil by means of a well-insulated cord, and when in use kept free from any possible conductor, as otherwise a portion of the current will be dissipated. From the character of the current it may be conveniently termed a high-tension oscillating current, or briefly H. T. O. As the term "secondary," however, has been applied to the static induced current, the one here described may, with equal propriety, be termed tertiary.

My use of this tertiary current has been chiefly in connection with chronic infiltrated eczema, rosacea, acne, localized pruritus, pityriasis capitis, the localized so-called "eczema seborrhoicum" and seborrhœa oleosum, in all of which resolution of the lesions has been accomplished more rapidly than by any means previously at my command.

Addendum. It has already been stated that if the terminals of the secondary coil of the transformer be grasped, one in either hand, there is absolutely no sensation or apparent muscular action. If, however, one hand be removed, say half an inch from one of the terminals, muscular contractions immediately ensue. This led me to intercalate Ranney's device for regulating the spark gap, and by means of it, generalized contractions can be controlled with the utmost nicety; ranging from those barely perceptible up to those that are hardly bearable. If asked concerning this current, "*Cui bono?*" my only present reply must be "*Quien sabe.*"

As a further experiment I placed the Ranney regulator in series with the primary coil of the transformer, and obtained a current apparently more energetic than when it was in series with the secondary, but both sparks and muscular contractions were more painful, and the cutaneous reaction was greater. It reminds me, in fact, of the effects obtained with a high-frequency machine in which an alternating dynamo is the source of energy; in other words, of the Tesla current. I have not as yet made any therapeutic use of this modification of the current, but would not be surprised if it should prove useful in some of the profounder lesions of the skin.

OBSERVATIONS ON THE SURGERY OF THE GALL TRACTS.[1]

By WILLIAM JONES, M.D.,

PORTLAND, OREGON,

PROFESSOR OF CLINICAL SURGERY, MEDICAL DEPARTMENT, UNIVERSITY OF OREGON; SURGEON TO ST. VINCENT'S HOSPITAL.

The surgery of the gall tracts may be said to have begun about twenty years ago. In 1879, Lawson Tait did his first cholecystostomy for removal of gall stones. This marks the opening of this field to the operations of the surgeon. Its development has been slow when compared with other departments of abdominal surgery. The complicated apparatus for storing and discharging the bile, together with much that was obscure as to its properties and uses, gave rise to many complicated problems in diagnosis and operative procedure, for solution by the surgeon. These difficulties have made progress slow and hesitating. These questions have engaged the attention of a multitude of workers all over the world and not only among surgeons. Their solution has been contributed to largely by the work of the physician, the physiologist, and the bacteriologist. Chemistry and pathology have lent their aid. The complete solution of any of them cannot yet be said to be an accomplished fact. A very great deal of work still remains to be done. The subject still remains a live one. As its investigation has been pushed along by a multitude of isolated workers, so it must be carried to something like finality in the same way.

Each year gives an added importance to the biliary apparatus as a factor in disease, as we understand it. Next to the appendix and the uterine appendages, it is the avenue by which serious disease most often enters the abdominal cavity.

Disease of this part mimics many other troubles. Many dyspeptic symptoms, nausea, vomiting, gastric pain, and discomfort are often traceable to this cause.

[1] Read before the Oregon State Medical Society, June 26, 1900.

Chills and fever simulating malaria are produced by infection here. Visceral cancer, as well as disease of the appendix and of the right kidney, is imitated.

In arriving at a diagnosis in cases of digestive disorders, in abdominal cases having localizing symptoms in the upper half of the abdomen, and in fevers of obscure origin and causation, disease of the biliary tract needs to be considered and excluded.

The clinical picture in disease of the gall tracts is very variable. The symptoms are numerous and their combinations almost infinite. The most constant symptom is tenderness on pressure over the location of the gall bladder. During the quiescent period no symptoms are present. The gall bladder might be filled with calculi, which would give no indication of their presence till one of them became engaged in the duct, and then there would be developed the symptoms of biliary colic.

As severe symptoms may be caused by the presence of a single stone as by that of a hundred. During an attack the pain may be widely diffused over the upper part of the abdomen or referred to the stomach, but the point of maximum sensitiveness on pressure will be over the gall bladder. There, too, will be the location of greatest muscular rigidity.

The attack may be so moderate, the pain of such a character and location as to be referred to the stomach, while the attendant nausea and vomiting seem to point to a gastric rather than a biliary cause. The differential symptom will be that the point of greatest tenderness on pressure will be over the gall bladder. If, during the attack, the common duct should be obstructed, jaundice will appear if the obstruction continues sufficiently long. If the obstruction lasts but a short time this symptom will be absent or so slight as not to be certainly recognized. Then another symptom is available. If the urine secreted during the attack or immediately after it be examined it will give the reaction for bile. This is an exceedingly valuable means. It can be used to advantage in certain cases of suspected biliary attacks, which from any reason cannot be personally observed by the surgeon. It will occasionally convert a well-grounded suspicion into a diagnostic certainty.

Not to be too curious as to first causes, I would say that gall stones are the cause almost invariably of the troubles we are now considering. Of course there must be a cause for the stones.

In operating on cases that have a history extending over a long period of time, quite often calculi are not found. Yet it is almost certain that they have been present, and by their presence and the traumatisms they have inflicted have worked changes in the biliary tracts attended by the most serious consequences. Stricture of the ducts causing permanent jaundice; or obstruction to the proper drainage of the gall bladder giving rise to overdistention, etc.; ulceration and erosion of the lining mucous membrane, changing the character of its secretion, making it thick, viscid, and difficult of discharge, and affording a culture medium for pathogenic bacteria, with the complex train of disturbances that an infection of these complicated passages implies—these are some of the consequences referred to.

In our operative procedures, it is not difficult generally to give relief, at least temporarily. The operation of Tait (cholecystostomy) will do this, and is the operation attended by the least risk. It will give permanent relief in many cases. In some, it will be followed by permanent fistula, in which case the relief will be permanent also, but with the annoyance of an external discharge. The closure of the fistula may be followed by a return of symptoms, a relapse, notwithstanding at the time of operation every stone was removed from the gall bladder, and the ducts were cleared. Other stones may form, or permanent changes in the bile passages, referred to before, may be present which will again cause trouble. I have at present under observation three patients who either have permanent fistulæ, or they suffer relapse when the fistulæ close.

We are extremely anxious to give permanent relief, and if possible by a single operation. This will be most certainly accomplished by permanent drainage of the gall bladder, by means of a cholecystenterostomy, after removing all stones from the bladder and ducts. This is most easily and rapidly done by means of the Murphy button. The button has the disadvantage that not infrequently it is not recovered. It is either retained or escapes observation when passed. In about half the cases in which I have used it, it has not been recovered. In none of these, however, have I noticed any evil consequences from it; nevertheless its recovery is always a source of satisfaction, and removes a certain anxiety as to the patient's future. When the common duct is free, the connection is best made, in my opinion, with the colon. This serves the purpose of draining the gall bladder, which is all that is necessary, and with the least disturbance of the natural arrangement of parts as they are in relation with each other. When the common duct is obstructed, then the connection should be made with the duodenum if the difficulties are not too great, otherwise with the small intestine high up.

Should it be demonstrated, as some assert to be the case, that the bile is excrementitious material and has no function to perform, then the colon will be the best point of attachment in all cases.

The ducts can be palpated throughout their whole course, by introducing one or two fingers though the foramen of Winslow. They can thus be engaged between the fingers and thumb, and any stones within them can be felt.

Judging from my own experience, and the published reports of others, patients with long-standing disease of the gall tracts are poor subjects for surgical operation, and surgical interference is attended by considerable risk. In such cases I believe it to be wiser to do first a cholecystostomy, the simplest operation, and the one attended by the least risk, leaving more radical treatment for another time, should it become necessary.

I would emphasize the following points:

1. The diagnostic value of the point of maximum tenderness on pressure, which is over the gall bladder at or near the costal margin of the ninth rib. This point in disease of the gall tracts corresponds in importance with McBurney's point in disease of the appendix.

2. The diagnostic value of the presence of bile in the urine excreted during or immediately after a very brief obstruction of the common duct.

3. Disease of the gall tracts is of very common occurrence, and is liable to be mistaken for other troubles which it closely imitates.

I would urge upon the physician the importance of these troubles and of their early recognition. He should familiarize himself thoroughly with their symptomatology, and train himself to recognize them promptly. The time is not very remote when it will be as much a matter for censure to fail to recognize the presence of disease of the gall tracts as it now is to overlook that of the appendix.

Bites.—Dr. K. Shimizu recommends the local application of an infusion of cassia occidentalis in insect and snake bites. He also praises "good ripe kaki" (persimmon) in obstinate vomiting of pregnancy and in diarrhœa.—*Medical Brief.*

THE SOLDIER'S RATION IN THE TROPICS —ITS USE AND ITS ABUSE.

By LOUIS L. SEAMAN, M.D.,
NEW YORK,
LATE SURGEON FIRST U. S. V. ENGINEERS.

In the great race for the survival of the fittest, wars are inevitable. Temporary checks may at times be brought about by the influences of civilization, and peace conferences may for the moment gratify the optimistic fancies of a visionary age. But the great truth remains that the natural termination of animal life is tragedy. In pre-historic and savage ages, this applied to the human as well as the lower animals. Civilization, in a measure, temporarily modified this through the influences of church and state and the conquests of medicine; to nothing, however, so much as to the science of medicine, which, since before the time of Hippocrates, has been steadily fighting and conquering the most terrible devastating enemies of humanity. Medicine has done far more than militarism. It has conquered or mitigated plagues and pestilences, which in single epidemics have destroyed more lives than the total of the combined armies of the world. In one outbreak of cholera in China thirteen million victims succumbed to this disease. History commits no greater injustice than the mention of a thousand generals to one physician. But what great purpose have the conquests of science attained for our armies?

Europe, to-day, is one vast military camp, the resources of each country taxed to the utmost limit to support the great living plants for human destruction, the armies and the navies; and America is not far behind. Thousands of millions of dollars are annually expended by the civilized nations of the world in the maintenance of great military schools and arsenals, for the education of men in the art of war, and in the manufacture of machines of human destruction, while comparatively little is being done in the study of those equally important subjects, preventable diseases in armies and the preservation of the health of "the man behind the gun." We go blundering on, expending over a million of dollars a day in our effort to destroy our human foes, while the more formidable adversary in the ranks, which history has shown to be five times more deadly than the bullets of an enemy, is left comparatively unheeded. Even the demand for the expenditure of a single million, or the cost of running our army for less than a day, for experimentation in the study of preventable diseases, and in the solution of dietary problems, so necessary for the preservation of the soldiers' health and energy, would be howled down by the short-sighted representatives of the people.

And what is the logical result of such mental myopia?

In the late Spanish-American war, fourteen men died of disease for every one that was killed by bullets.

Every death from preventable disease is an insult to the intelligence of the age. When it occurs in an army, it becomes a crime. The first responsibility of a government in times of war or peace, should be the proper care of its guardians. The state deprives the soldier of his liberty, prescribes his exercises, equipment, dress, and diet. It should, therefore, give him the best sanitation and the best medical supervision that the science of the age can devise. The morals of most wars are *cash*. From a moral then, as well as from an economical standpoint, the state should guard the soldier's health, for nothing is more costly in war than disease, and, after war, than the pension claims.

A personal experience in two of the latest tropical wars, and a study of the statistics of others, led the writer to the conviction that the cause most prominent in bringing about the conditions most favorable for the development of preventable disease in both these wars resulted from the misuse of food. And that this object-lesson may not be without its advantage to other lands is the *raison d'être* of this paper.

Attributing to climate the diseases of the tropics is an error due to ignorance and custom. The vast majority of ailments accredited to climate have their origin in the use of improper foods, in over-feeding, or in the abuse of stimulants.

During the past two years, it has been my misfortune to see two great armies, one in my own southern country in Cuba and Porto Rico, and one in the Philippine Islands, largely invalided through errors in improperly subsisting the troops, and through hyperalimentation. When whole regiments were suffering from stomach and intestinal catarrhs, diarrhœas, and kindred ailments (and I have seen over seventy-five per cent. of an entire command in this condition at one time), they were subsisted on a ration of rich meats, pork, beans, tomatoes, and other foods, that aggravated the diseases, crowded the hospital tents, and left the men weak and emaciated, so that their return to health was a prolonged struggle.

By this method a vicious circle was established, the diseases grew by what they fed upon— the utter unsuitableness of the ration creating the trouble and intensifying conditions which often resulted fatally, and which were always to the detriment of the soldier. Taps, and the last volley, were often the only reward many a poor soldier received for his patriotism.

From an extended observation of the commissary service of nearly every army of Europe, and those of China, Russia, and Japan, I believe that the ration served to the American soldier in the tropics was the richest, most expensive, and by reason of its richness the most unsuitable. The potential energy of this ration as represented in caloric units was 4,448; that issued to the British soldier in a temperate climate is but 2,800, while the caloric units in the ration of English prize-fighters, as given by Gillespie of Edinburgh, is but 2,200. It is an old saying that "The ration wins the battle." As furnished to the army, it was an excellent winter food, rich in nutritive and caloric power under a low temperature; but for a tropical land, the excess of carbon furnished by it to the lungs, over and above that which they could dispose of, imposed upon the liver and kidneys additional duties of elimination, producing congestions, fermentation and catarrhs, dyspepsia and lithæmia, glycosuria and phosphaturia, interfering with metabolism, and creating conditions favorable to bacterial development, together with almost the entire train of disease which crowded the army hospitals. In phosphaturia, especially, the nervous system is deprived of the salts necessary for its proper functions, which deprivation to the soldier not infrequently resulted in mental disturbances that in many instances ended in suicide or insanity. How little the climate was responsible for these cases may be inferred from the extreme rarity of sunstroke in the tropics. The writer, after years' experience, has yet to see his first case of this nature there, although he has numerous friends, English, German, French, and American, residing between Bombay and Shanghai, who have lived in those lands for periods varying from twenty to forty years, and who have maintained excellent health throughout the entire time, simply by regulating their foods and exercise. They could have lived equally well in the arctic zone by following similar precautions.

Dr. Ordronaux, a prominent surgeon of the American army in the war of the Rebellion (1861–64), said: "By a proper disposition of his diet, man lives as healthfully under the equator as under the pole. The East Indian with his rice and yams, and the Esquimau with his seal blubber and putrid fish, are both

healthy enough in their respective climates, but let them once change residences without changing their diet, and what would be the consequences? The Esquimau would be attacked with putrid fever, and the West Indian would die of inanition.

"We perceive from this the absolute necessity of modifying all forms of diet in such a way as to accommodate them to the physiological requirements of the varying seasons. For habit is not acquirable as against the laws of chemical combination, and no man can become habituated to doing that with impunity which, being a violation of the physiological laws of his system, is by its frequent admonitions of pain notifying him of the evil about to overtake him."

"Habit is not acquirable against the laws of chemical combination." The soldier cannot disregard these laws, even under orders. An army regulation may provide a ration which violates nature's law, but no human power will permit a soldier to subsist on it and maintain his health.

The experiences of the British in Burmah and the West Indies, and the French in Algeria, forcibly illustrate this. In the first Burmese war, for six and a half months the troops were subsisted on salt ration almost exclusively, and forty-eight per cent. of them perished within ten months, principally of scorbutic dysentery, while in the regiment of Cameronians seven hundred out of nine hundred were invalided from the same cause in two months. In both instances these diseases were induced by an almost exclusively salted diet, which not only irritated the intestines, but did not furnish sufficient nutriment to the system. It was observed in the West Indies, in the Leeward and Windward Command, that after an issue of salt ration five days in the week, the mortality was twenty per cent. When the issue was reduced to two days per week the mortality fell to two per cent. An excess of fresh meat also produces intestinal derangement. This was strikingly shown by Lamaran in the French campaign in Algeria, when the men ate excessively of captured mutton, and rapidly succumbed to intestinal disease. The same condition prevailed in the American army during the Civil War. It was noticed that immediately following a raid in the enemy's country and the capture of quantities of live stock, which was given to the men in excessive amounts, an epidemic of intestinal catarrh or dysentery invariably followed.

Simple catarrhal affections of the stomach and upper intestinal tract, not resolving rapidly, will lead, under an unsuitable dietary, to congestion of the liver, with all the dangers attached to such a state in a climate where the natural antiseptic of the intestine is of such paramount importance. The reduction of quantity in bile will lead to auto-intoxication and extension of the processes of inflammation, until the entire intestinal tube may be involved; and jaundice, duodenitis, enteritis, or colitis is developed, conditions which offer an open door for the entrance of micro-organisms.

The pathological features of the cases on which I was fortunate enough to hold autopsies, whether the causes of death had been pronounced intestinal catarrh, hepatitis, duodenitis, typhlitis, enteritis, enteric or typhoid fever, colitis, dysentery or diarrhœa associated with malaria, presented many similar characteristics. The liver was almost invariably congested. The mucous membrane of the intestine was pale, and covered with a thick, tenacious, adherent mucus; the mucosa was hypertrophied, often deeply congested and ulcerated; in two instances these ulcerations almost encircled the entire intestine. The toughess of the opaque secretions obliterated the intestinal glands, causing atrophy and thus interfering with absorption and metabolism. The solitary follicles stood out with prominence, and the patches of Peyer were distinct, often with minute ulcerations on the surfaces, notwithstanding many of the cases in which they were found presented no characteristic typhoidal temperatures, and during life failed to respond to the Widal reaction.

From earliest history, experience has shown that, in time of war, disease was a far more deadly foe to an army than were the bullets of an enemy. In the war of the Crimea the French lost in killed twenty-one thousand, and from disease one hundred thousand, or about one from bullets and wounds to five from disease. The proportion of losses of the British from disease in that campaign ran a little higher—six having died from disease for every fatality from bullets and wounds.

In the American war with Mexico nearly the same proportions were maintained—five fatalities being ascribed to disease for every one resulting from bullets or wounds. So too, in the war of the American Rebellion, lasting four years, the rate of five to one remained unchanged. In round numbers five hundred thousand perished in hospital wards from the more fatal enemy disease, and one hundred and one thousand fell on the field or died as the result of wounds.

But it has been reserved for the Spanish-American war in the tropics to cause a blush of indignation at the apathy that permitted preventable diseases to play such havoc with its army. In a campaign, the actual hostilities of which lasted from July 1st to August 18th, about six weeks, the mortality from bullets and wounds was two hundred and sixty-eight, while that from disease reached the appalling number of thirty-eight hundred and sixty-two, or about fourteen to one. With proper subsistence and sanitation, these proportions for such a short service, and with men recruited after rigid examination and accepted on account of their splendid physical development and health, should have been reversed.

In the limited scope of this paper it is not purposed to discuss the various ration tables of the armies of the world, or the relative merits of each article of diet. This may be found in the elaborate works of Parkes, Yeo, Carpenter, Ranke, Atwater, Rattray, Eijkman, Mourson, Cohnheim, Notter and Frith, Church, Duncan, and others who are authorities on foods. But I wish to call attention to the dangers in tropical environment resulting from overtaxing the digestive system of healthy men from temperate climes, by the excessive use of meats and fats, which require more oxygen in their metabolism, and thereby create more heat through the activity imposed upon the internal organs in their digestion and elimination.

In addition to tissue repair the ingestion of food is to accomplish two results—the development of body heat, and bodily motion or energy. The mutual relation of income and expenditure has been calculated to a fine degree of exactitude. Ranke's well-known tables show that one-sixth of the total income of food is expended in mechanical force, and five-sixths in producing heat. Carpenter on this question (the lesser production of body heat where the external temperature is high, as in the tropics) says: "Every change in the organic components of the body in which their elements enter into new combinations with oxygen must be a source of the development of heat, and as a considerable portion of the carbon dioxide and water exhaled in respiration is formed within the body by the metamorphosis of its own tissues, and since the metamorphosis is promoted by the active exercise of the nerve-muscular system, it follows that in animals whose habits are peculiarly active, living in climates in which the surrounding temperature is high enough to prevent any cooling influence, the combustive process thus maintained may be adequate for the maintenance of the temperature of the body at its own normal standard. Hence, it appears that we do not want to provide for the heat of the body in the tropics, but

only for the work done when there is a peculiarly active life."

Carpenter says: "The general experience of inhabitants of warm climates is in favor of a diet chiefly or entirely vegetable, inasmuch as such diet affords an adequate supply of albuminates in combination with the other classes of foods without affording more fuel than the system requires."

These statements have an especial interest when considered in conjunction with the highly nitrogenous and heat-producing elements of the United States field ration, which contains nitrogen 18.12 gm., protein 113.26 gm., fats 218.26 gm., and carbohydrates 489.08 gm., and represent in caloric units 4,448.

The average of four dietaries of natives in the tropics when at hard labor (of the West Indies by Maurel, the Abyssinian soldier by Labicque, the cooly in British India by Church, and the Malay by Eijkmann, brought up for comparison to the common standard of body weight, 145 lbs., of the European by Munson, in an admirable essay on this subject) was found to contain of nitrogen 12.18 gm., protein 76.18 gm., fats 40 gm., carbohydrates 560.01 gm. and represented in caloric units 2,900.

Compared with the above average the United States ration represents an excess of nitrogen 5.94 gm., protein 36.08 gm., fats 178.26 gm. and of caloric units of 1,548, while in the principal and easiest energy-liberating element, the carbohydrates, there is a deficiency of 80.93 gm.

Life in the tropics is found to produce the following conditions:

1. Increased body temperature, amounting on an average to over 0.5° F.

2. Loss of body weight due to imperfect oxygenation and the destructive effect of continued heat, amounting to over eight per cent. in the first year.

3. Diminished cardiac action due to low arterial tension and the relaxed state of the capillaries, resulting from the loss of fluids by increased perspiration.

4. Lower pulse rate amounting to three per cent.

5. Reduced pulmonary endosmosis on account of the rarefaction of the atmosphere and the low arterial pressure.

6. Diminished urinary secretion owing to increased perspiration, amounting to thirty-three per cent.; and a higher specific gravity of the blood in consequence.

7. Diminished excretion of urea by the kidneys amounting to ten per cent.

8. Increased secretory activity of the liver caused by the irritation resulting from the loss of fluids and relaxation of the capillaries, and the decreased elimination of urea by the kidneys. This increased activity frequently amounts to congestion, which, if continued, soon becomes chronic with danger of impaired function.

9. Diminished secretion of saliva, mucus, gastric and pancreatic juice, and bile, in consequence of increased perspiration and the higher specific gravity of the circulating fluids.

10. Dependent on these are dryness of the throat and fauces, exaggerated thirst, weakness of appetite, and impaired digestion.

In order to cope successfully with these conditions it is necessary to relieve the digestive apparatus of all superfluous labor. The food should be well cooked to prevent alimentary fermentation, and should contain as little of the albuminoid principles taken from meats and fats as is compatible with the repair of the system. Meat, in the fresh state, being the most perishable of all foods, should, for campaign requirements, be replaced as largely as possible with dried and smoked varieties. The creosote in smoked beef being a gastric stimulant and intestinal disinfectant, when proneness to diarrhœa exists, is a decided advantage. Salt and tinned meat is objectionable. The nutritive value of salted meat is reduced over one-third owing to the solution of the albuminates by the chloride of sodium, and is rendered less digestible through the hardening of its muscular fibre; and tinned meats produce after continued use impairment of digestion. On the contrary, smoked meats are not prone to decay, they retain their nutritive qualities, are easily digested, concentrated, and far more portable for field use.

The energy of the system should be derived as largely as possible from easily digested carbohydrates, instead of from meats and fats. The metabolism of both nitrogen and fat produces much unnecessary heat, through the splitting up of the proteids and the emulsification of the fats. Carbon necessary for nutrition can be provided either in the form of fats or carbohydrates.

Fats are more suitable for tissue growth and repair than carbohydrates alone. A large proportion of fat, however, is as a rule not well tolerated by the digestive organs for continued use, except under conditions of climate like that of the Arctic regions.

Dujardin-Beaumetz regards the average daily allowance of fats as 55 gm. The great purpose of fat in the food is to diminish albuminous metabolism, and it is, therefore, regarded as an albumen-sparing food.

As stated by Baumer, "If flesh alone be given, large quantities are required in order that nutrition and waste may balance one another, but if fat be added the demand for flesh is less."

External temperature influences the metabolism of the hydrocarbon and therefore the amount of carbon excreted. The lower the temperature, as long as that of the body itself is maintained, the greater the metabolism of non-nitrogenous foods and the greater the amount of carbon discharged from the body. In higher temperatures the reverse conditions prevail—there is less metabolism and less carbonic acid exhaled; therefore, excepting for the actual necessities of the system, fats should be avoided in hot climates.

Natural appetite or instinct prompted the avoidance of fatty food by the troops in Porto Rico, Cuba, and the Philippines. Their aversion to bacon, the best form in which fat can be supplied for campaign use, led practically to a waste of this article, except as it was used for culinary purposes.

Carbohydrates, while having much in common with fats, have additional advantages. They serve the same purpose of checking albuminous waste, and, like the fats, they are resolved by combustion within the body into carbonic acid and water. They also yield heat and energy, but do not enter into the structure of the tissues. All carbohydrates are converted into glucose before absorption, and in this form are more readily metabolized than fats or albuminates. Bauer showed that carbohydrates, even when administered in great excess, are almost completely destroyed within the body. He maintains that, owing to the facility with which they are metabolized, they protect other foods from destruction. Owing to the ease with which they are oxidized (as they contain hydrogen and oxygen in the proportions to form water), the carbon is easily liberated for the purposes of energy, and with less production of internal heat. For this reason they are our most valuable factor for the production of energy in the tropics, as they impose less labor on the organs of digestion.

Of the cereals which must supply a portion of the carbohydrates, those indigenous to the tropics are better than those grown in temperate zones, as they contain less nitrogen. Of these maize, rice, and the native lentil, when well cooked, are preferable. In a mixed diet in which fat and albumen are supplied from other sources, rice, on account of the easy digestibility of its starchy components, is especially valuable.

Napoleon, commenting on the terrible trials of the

Moscow campaign, mentions that of all his army the Italian troops withstood the hardships best. They were subsisted on a ration made up almost exclusively of vegetables and cereals. Leonidas and his little Spartan band defended the passes of Thermopylæ on a diet of lentils. The winner of the late international race at the Olympian games at Marathon trained on the same food, the lentil. All were carbohydrate fed.

The advantages of sugar are only now beginning to be appreciated. When energy is to be liberated rapidly with the least tax upon the digestive system, sugar, an almost pure soluble carbohydrate, would seem to be the ideal food for the purpose.

Nature's prodigal supply of sugar-cane, and low-heat-producing but nourishing fruits in tropic lands, would seem to indicate their peculiar adaptability for the particular requirements of inhabitants of hot zones.

The bee and the colibri, whose marvellous endurance is the wonder of the physiologist and philosopher, derive their power almost exclusively from sugar. Every one who has seen the humming-bird suspended in space for hours, with wings moving with lightning rapidity, flying from flower to flower, drawing from the chalice the sweetened dew, must have wondered at the marvellous conservation and correlation of force that enabled it to perform such sustained effort; the motive power was sugar.

In the Philippines the cavalry horses imported from America became emaciated and refused to eat, until it was discovered that molasses or sweetened water sprinkled on the coarse grass or hay made it palatable. When fed to them in this form they flourished and grew sleek and fat. A soluble pure carbohydrate, sugar, had supplied the deficiency. Among the troops in Porto Rico and the Philippines whose appetites and digestions had become impaired, there was a craving for candies and sweets which was astonishing, all due to the same physiological reason, the instinctive desire for an easily metabolized, energy-producing food which these articles supplied. Cyclists, on long "tours de force," have demonstrated what can be accomplished on a ration containing little else than carbohydrates. In these record-breaking trials, extending over periods of many days, the expenditure of energy is nearly continuous. The intervals for rest or sleep are very short, and exhaustion can be counterbalanced only by the most easily metabolized diet. Experiments with the ergostat have demonstrated, by the use of sugar, the rapid liberation of energy following a state of extreme exhaustion. Sugar relieved fatigue more rapidly than other foods.

The excessive use of sugar, however, with a mixed diet, interferes with the digestion of proteids, in diminishing the secretion of hydrochloric acid; but, when the supply of meat and fats is restricted, hydrochloric acid is not required to such an extent, and consequently sugar can be used more liberally. In comparison with other foods, sugar could be regarded as a refined fuel for the system, just as alcohol would be if used for fuel for an engine. In their easy metabolism they liberate energy, and in their perfect combustion they leave no ash or waste products.

Tea and coffee contain the identical alkaloids, theine and caffeine; but for campaign purposes tea has many advantages. When compressed in cakes it is concentrated and easy of transportation. Two minutes are sufficient for its infusion, and if taken in a weak solution, as it always should be, the large quantity of palatable sterilized water introduced into the system forms not only a refreshing beverage but stimulates the processes of digestion, and increases remarkably the soldier's power of enduring great fatigue in hot climates.

Curry is a valuable addition to the usual condiments (pepper, salt, and vinegar). It aids digestion in stimulating intestinal secretion, and acts as an anti-fermentative.

A liberal ration for the soldier in the tropics could be supplied in the following articles:

Fresh meat 10 oz. or its equivalent in dried and smoked beef, bacon 2 oz., flour 12 oz., rice, lentils, or maize 4 oz., succulent and green vegetables 14 oz., dried fruits 2 oz., sugar with chocolate 4 oz., tea and condiments including curry, salt, pepper, and vinegar 3 oz.

This allowance represents about 40 grains of protein, 15 of nitrogen, 83 of fat, and 540 of carbohydrates, and equals 3,300 caloric units, or more by 400 than the average given in the dietary quoted by Munson for men at hard labor in the tropics.

From this list an extremely light, portable travel ration could be selected. By doubling the quantity of sugar, the bulky carbohydrates (the vegetables, fruits, and cereals) could be omitted, and the energy-supplying quality of the ration maintained at almost its full standard.

If supplemented by an occasional indulgence in fruits and vegetables to be found *en route*, to supply vegetable salts and acids, an army could subsist for months under severe physical strain, and maintain its health and vigor. The pea sausage, as used by Kitchener in his campaign from Khartoum to Omdurman, has amply demonstrated this.

A consideration of this topic by the International Congress may not seem pertinent to its members; but just now, with the allied armies of Christendom gathered in a foreign clime for a common purpose, with the Caucasian arrayed against the yellow races—the Occident against the Orient, the temperate zone against the tropic, and the prestige or preservation of modern civilization the tremendous issue—the study of these problems, on the successful solution of which victory or defeat may depend, becomes of paramount importance.

18 West Thirty-first Street.

Subarachnoidean Injections of Cocaine as a Substitute for General Anæsthesia in all Operations Below the Diaphragm; with Report of Nine Cases.—John B. Murphy says that an American, Dr. Leonard Corning, demonstrated in 1884–85 that anæsthesia could be produced in this way. Oberst, Bier, and others later took up the matter, but the man who really advanced it as a practical anæsthetic is Tuffier. The advantages of the procedure are: ease of application; thorough analgesia of all the tissues below the diaphragm; the retention of the sense of touch; absence of the reflexes; consciousness of the patient; avoidance of the primary intermediate and secondary sequences of the anæsthetic, as cardiac phenomena, pulmonary lesions, and renal disturbance. Whether the cocaine will be found to interfere with the function of other organs time alone must determine. Tuffier, in his extensive experience from last November to the 10th of August, has had no untoward results of any kind, and has secured complete analgesia in every case. Hysterectomies, salpingectomies, nephrectomies, pylorectomies, cholecystostomies, and operations of that class are performed by him regularly in accordance with this method. The author gives the technique of the method, and reports nine cases of his own.—*The Chicago Clinic*, September, 1900.

Venomous Snakes, their Bites, and How to Treat Them.—Joseph McFarland says that, briefly outlined, the treatment of snake bite is (1) immediate interruption of the circulation of the bitten member, so as to prevent absorption of the poison; (2) free incision

and enlargement of the fang wounds and forcible suction to extract the poison; (3) hypodermic injection of three to six drops of a fresh ten-per-cent. watery solution of chloride of calcium into about a dozen different areas about the wound; (4) strychnine given hypodermically to stimulate the respiratory centre; (5) immediate and frequently repeated hypodermic injections of 10 to 20 c.c. of the antivenomous serum, or, as Calmette calls it, "antivenene." The most urgent need of the patient is for the immediate, unlimited administration of antivenene. It would be a wise precaution for persons whose travels or occupations keep them in continual danger of snake bites to provide themselves with the remedy and carry it with them. There are many whose occupations of berry-picking, lumbering, mining, hunting, engineering, etc., carry them into wild and snake-infested countries, to whom the possession of a snake-venom antitoxin with even a limited application would come as a boon.—*International Medical Magazine*, September, 1900.

Permanganate of Potassium as an Antidote to Opium Poisoning.—W. K. Gatewood saw a negro child, aged eighteen months, one hour after taking an overdose of laudanum, exact quantity not known. The child was cold and clammy with slow and feeble respiration. The stomach was washed out and one-quarter grain of the permanganate was injected into the thigh. In half an hour there was marked improvement in respiration and circulation. In another hour strong coffee could be taken, while in the course of twelve hours the child was out of all danger and able to walk. Gatewood does not believe that stomach washing alone would have saved the case.—*Richmond Journal of Practice*, August, 1900.

Hemorrhage Occurring after the Menopause.—E. C. Davis writes that at the time of the menopause atheromatous changes are likely to take place in the blood-vessels, malignant diseases make their appearance, and the atrophic changes of the tissues become observable. After menstruation has ceased, any hemorrhage from the uterus is always pathological, the causes of hemorrhage at this time being granular endometritis, atheroma of uterine blood-vessels, vasomotor relaxation, uterine polypus, uterine myofibromata, and carcinoma of the uterus. Of this last new growth, hemorrhage is the danger-signal which, if appreciated by the physician, may result in years of comfort and health to the victim. If neglected, however, a horrible death awaits the patient. During the early history of carcinoma, the tumor is local and circumscribed, but later becomes hopelessly disseminated. The cervix is the most frequent seat and epithelioma the most common form of malignant tumor. The history of hemorrhage after the menopause with offensive discharge is almost pathognomonic of malignancy. The most rational treatment is complete removal of the diseased uterus, with appendages, before extension has taken place into the surrounding tissues.—*Obstetrics*, September, 1900.

An Anomalous Case of Central Hemorrhage, Connected with Increased Pressure in the Ear due to Violent Coughing.—Macleod Yearsley reports the case of a woman aged fifty-four years, who two weeks previous had a violent attack of coughing, during which she experienced vertigo, deafness, tinnitus, and loss of memory. Vertigo continued twelve hours. The next morning there was some weakness of the right arm and leg, and slight left facial paralysis. Symptoms gradually abated, and when she was seen by the writer the deafness had almost entirely disappeared, while the vertigo persisted to only a slight degree. Tinnitus persisted only in the left ear. The tuning-fork on the vertex was heard better by the left ear; Rinne's test was positive on both sides. Bone conduction was impaired on both sides, about twenty-five per cent. being lost. Both membranes were dull, opaque, and indrawn, but there were no signs of either old or recent rupture. Movement to the pneumatic speculum was good on both sides. Treatment consisted in counter-irritation and dilute hydrobromic acid in drachm doses three times daily. Gradually all evidences of the attack disappeared until only very slight deafness remained.—*Journal of Laryngology*, August, 1900.

Chorea and Leukæmia as Indications for the Induction of Labor.—According to Merttens severe chorea occuring during pregnancy is a sufficient cause for the induction of premature labor; in confirmation of this opinion he reports a case of the utmost gravity which was undoubtedly saved by this means. Chorea intervening in the course of gestation is undoubtedly of reflex origin and emanates from uterine disturbances, hence the necessity for prompt treatment. Not every case requires such a heroic measure; but when the convulsive seizures continue during the night and prevent sleep, which is unusual in the ordinary forms, abortion is indicated. Another condition justifying the premature emptying of the uterus is a complicating leukæmia. In the case reported, however, the author was not so successful as in the preceding one, and death occurred soon after the operation, which might have saved life if it had been performed earlier. —*Monatsschrift für Geburtshülfe und Gynäkologie*, September, 1900.

On the Accentuation of the Second Sound in the Pulmonary Area; Skoda's Sign.—J. F. O'Carroll thus states the views of Skoda on the point named in the title: "In many cases of disease involving the left side of the heart, the second sound is heard with marked clearness and even accentuation at that spot on the chest wall at which the pulmonary artery comes nearest to the surface. The sound is therefore in the pulmonary artery. Disease of the valves of the left heart induces a tendency to more or less delay in the circulation through the lungs: the pulmonary system is in fact over-full; there is, therefore, a condition of engorgement of the pulmonary artery, and consequent slamming, so to speak, of the pulmonary valves, indicated by an exaggerated noise or accent." O'Carroll objects to the statement that a vascular murmur heard at the surface is necessarily produced by that vessel which happens to be most superficial at the point of observation. With regard to the engorgement of the pulmonary vessels he states that, other things being equal, the loudness of the diastolic note will be in proportion to the amplitude of the recurrent wave from the periphery in the pulmonary artery. But in mitral incompetence or stenosis the pulmonary artery tends to be still fuller than it is in health, and in health it is, as the physiologists teach us, somewhat distended or over-full. In disease of the mitral valve, therefore, the artery wall is stretched in the presytolic period nearer to its limit of elasticity, and therefore its range of post-systolic recoil is more limited. That is to say, the amplitude of the recurrent wave will be less than normal, and the intensity of the second sound should be correspondingly diminished. Practically the accentuation is absent in many cases in which, according to the theory, it ought to be present. It is present, on the contrary, in many cases in which there is not the slightest reason to suspect either heart disease or tendency to delayed pulmonary circulation. Finally there are certain cases in which the accentuated sound is produced probably in the aorta, and not in the pulmonary valve at all.—*Dublin Journal of Medical Science*, September, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

THE INCREASE IN SUICIDES.

SELF-DESTRUCTION has probably been practised from the very earliest times. The popular belief is that the Romans and Greeks held the view that a man had a right to end his life if he so wished, and that, regarded from a moral aspect, he was not only absolved from blame, but in terminating an existence tiresome to himself and useless to the community at large, performed a meritorious and courageous action. Cicero was an upholder of this doctrine, and said that it is living according to nature in a wise man to take his leave of life when he is in the midst of abundance, and that he is a fool to prolong it if he is miserable. Other famous Romans and Greeks spoke to the same effect. Notwithstanding these examples, there is no complete evidence that suicide was looked upon with favor by the mass of the inhabitants of ancient Greece and Rome, or indeed even by the greater portion of their celebrated men. Horace, Lucretius, and Plato all declaimed in eloquent language against suicide. There is, however, little doubt that in latter and declining days of Rome, when her richer citizens, sated with luxury and enervated by every kind of indulgence and vice, and above all upheld by no religious sentiments, tired of life, sought a refuge in the oblivion of the tomb. Mr. G. Styles, of Union City, Mich., who contributed to the *American Journal of Insanity* for July last an article on suicide, refers to the fact that in a former age the city of Marseilles kept constantly prepared a hemlock mixture, so that any one tired of life might obtain it at the public expense, the only condition being that the intending self-murderer should appear before the council of the six hundred, and give an account of the reasons why he desired to die. Christianity has always set its face against suicide, and thus when the Christian religion supplanted the old faiths of European countries, and when those who killed themselves were adjudged guilty of a heinous crime, self-destruction decreased. Unfortunately, however, within recent years the number of suicides has enormously increased and is still increasing. The cause of this weariness of life is undoubtedly to be found, to some extent, in our advanced civilization, which has enlarged our ideas of enjoyment at a more rapid rate than it has supplied us with the means of gratifying them. Progress in education is another powerful adjuvant to the general feeling of discontent, insomuch as the poorer classes have learned sufficient to be dissatisfied with their lot. But the decay of religious sentiment—which is to be observed in all those countries which are in the foremost rank as regards knowledge—and especially the growth of scientific knowledge have perhaps conduced more to the spread of suicide than has any other single cause. That the decadence of orthodox belief is an important factor in the increase of self-murder is demonstrated in great cities like Paris, Berlin, and Vienna, where agnosticism is rampant, and where the greatest number of suicides occur. Dr. Ireland traces the greater portion of the causes of suicide to severe strain upon the nervous system which may be the outcome of a multiplicity of causes. Among these causes may be mentioned the increased strain of modern life upon the nervous system. Again, the contagious effect of crime, fostered by the newspapers or, as *The Lancet* puts it, operating upon those whose "pithecoid imitativeness" is part of their "retrocedent organization," is sufficiently established to enhance the regret that lay journalism within its undoubted province of describing current events inevitably panders to the morbid craving, of which the said imitativeness is an expression, and neutralizes most of its undoubted benefit by helping to diffuse the criminal contagion. The psychological factor of vanity must surely be taken into account in discussing suicide, and this human weakness is greatly influenced by the modern newspaper. The following are the mean annual rates per 1,000,000 population of some of the European countries. Saxony, 1861–70, suicides 281; 1871–80, suicides 325; 1881–84, suicides 370; 1885–88, suicides 333. In Denmark during the same periods 283, 266, 249, 259. In France, 129, 161, 189, 212. In Prussia, 127, 153, 198, 204. In Belgium, 61, 81, 107, 116. In Sweden, 80, 86, 96, 110. In England and Wales, 66, 70, 74, 78. In Norway, 82, 70, 68, 66. Italy, 27, 37, 37, 48, 48. It will be observed with the exception of Norway the suicide mortality rate has increased, and in most countries very considerably within recent years. The diminution in Norway is attributed, says the *Nineteenth Century Review*, to the energetic attack which the Norwegian government has made on alcoholism. The same journal says that, in the case of Italy particularly, emigration accounts to some extent for the low rate prevailing there. It is evident that emigration provides an outlet for a great deal of misery and constitutes a hopeful alternative to suicide. Most persons would naturally suppose that the season of winter would be most prolific of suicides. It is the season of great difficulty for the poorer classes, often of bitter distress. Contrary, however, to this expectation, the months of May, June, and July are the ones in which the largest number of suicides occur. The connection of sex and suicide is an interesting study, and, as might be imagined, many more men take their own lives than women, the proportion being four to one. Marriage exercises a most beneficial effect in curbing the desire of self-destruction, the probability of bachelors committing suicide being 2.7 times that of married men of same age. Soldiers are more prone to self-destruction in all countries of Europe, France alone excepted, than those engaged in civil life. The rate of suicide mortality in the United States is

1 in 35,000. Dr. D. R. Dewey finds that in the New England States since 1860, suicide has increased about 35 per cent. In Massachusetts it has increased in thirty years, 1860-90, from 70 to 90 to the million living, and in Connecticut from 61 to 103 per million. A steady increase of self-destruction is common to the whole civilized world.

THE MALARIA PROBLEM.

Malaria is perhaps the most deadly disease that attacks man. In tropical countries it certainly claims more victims than does any other disease, and according to some authorities it kills as many persons as do all the other tropical maladies put together. For these reasons and for the especial reason that the white man is invading and making his home in the tropics to a greater extent every year, it is of the utmost importance that means of successfully combating malaria should be devised at once. The solution of the malaria problem will go far toward paving the way to render residence in the tropics not only harmless, but even healthy to the person of Caucasian race. The first step to be taken in fighting any disease is to discover its origin. This endeavor, owing to the researches of a long line of investigators commencing with the American scientist King and ending with the British Manson and Ross, has culminated in a great success. There can now be but little if any doubt that to the anopheles species of mosquito is mainly if not entirely due malaria in whatever part of the world it may occur. Attention was drawn in the Medical Record, October 6th, to the further substantiation of this theory by negative proofs in the Roman Campagna and by positive proofs by inoculation experiments in London. The next step in the battle against this disease, seeing that its etiology has been made plainly evident to the satisfaction of most scientific men, is to initiate methods to protect against the attacks of the malaria-bearing mosquito, and what is of far greater import, to extirpate these insects if possible. The means of protection at night, at least, is easily procurable, and consists in using a mosquito net, so made and arranged that no insect can bite through its meshes or enter through casual openings in its structure. The question of extirpating the anopheles mosquitos is, of course, one of infinite difficulty, but it should be remembered that it cannot be insurmountable. Situations which have seemed to present as many and as great problems have been cleared by the genius and inventiveness of man. This country in her newly acquired tropical possessions, and in some of her Southern States, has territory in which malaria flourishes, and is in consequence directly interested in the successful solution of the malaria problem. Dr. Manson, referring to this fact, makes the following statement published in the *New York Herald*, Sunday, October 7th: "When I suggested six years ago that malaria could be carried in the proboscis of a mosquito, American scientists were the first to grasp the reasonableness of the idea and believe in it. The gratification I have consequently always felt has been brought forcibly home to me in the light of our recent demonstrations. In fact, America herself has now to grapple with an evil which has baffled the authorities in England's tropical possessions. While this is a matter of regret and deep concern, it is a promising phase of the situation from our standpoint. We believe that inventive American enterprise, now that that country has an incentive of its own, will manifest itself in a practical scheme of mosquito extermination. Thus far we have contented ourselves with prevention and defence, but the results have necessarily been doubtful. The evil cannot be eradicated save by radical measures. There must be a positive campaign against malaria-breeding conditions, and fame and fortune await the man who will devise either machinery or a system of disinfection which will spell death for the mosquitos." Of all civilized countries, Italy is the only one that suffers within her own borders to any extreme degree from the ravages of malaria, but if accounts may be relied upon, the malady is an absolute scourge to a large portion of that peninsula, and one of the most potent causes of the grinding poverty prevalent among its people. M. Emile Bertaux, writing in the *Revue des Deux Mondes* on the subject, goes into the matter at length, and after giving a series of statistics from various sources demonstrating the mortality and sickness in Italy due to malaria, proceeds to remark: "To-day London, Paris, and Berlin have no anxiety on the subject of malaria, except for colonists and soldiers sent out to the establishments in South Africa or Asia. But since the annexation of Naples to the kingdom of Italy, and the placing of the capital in the midst of the Agro Romano, the disease, which for England, France, and Germany remains a colonial disease, has become for the kingdom of Italy a national disease. Sad destiny for an energetic and ardent people, whose sobriety up to the present time has preserved it from the ill effects of the drunkenness which the populations of the north did not know how to resist. The malaria alone produces the same ravages in Italy that the swamp fevers produce in Tonkin and Madagascar, and which alcoholism produces in France." Therefore it is Italy who will benefit in the first instance and most greatly if the outcome of the experiments amidst the Pontine marshes can be put to a practical use. The Roman Campagna was once a fertile tract of land and able to support a large population; it is now entirely, through the agency of malarial fever, a region of barren desolation, whose stricken inhabitants drag out a weary, wretched existence. If the sanguine expectations of those who are firm believers in the malaria mosquito theory are fulfilled, the Campagna and those other parts of Italy to which the fever has brought ruin may once again be restored to their pristine prosperity. At any rate, as pointed out by the London *Times*, the experience of the English fen districts shows that the ague-carrying anopheles disappear before drainage and cultivation, and when it has once been shown that cultivation can be securely practised under a condition no more onerous than that of sleeping in a mosquito-proof hut, there can be no doubt that Italian capital and enterprise will speedily avail them-

selves of the great opportunity which will be afforded them, and that a tract of land, which roughly measures ninety by forty miles and is scarcely used except for autumn pasture, will be reclaimed for all the purposes to which it can be applied.

There can be no doubt that, when an effectual method has been found to destroy the pernicious mosquitos wholly, the greatest drawback to life in the tropics will be removed, and that a new era of progress in all the arts of civilization will be inaugurated. In the MEDICAL RECORD for some considerable time an effort has been made to impress the American men of science and physicians with the paramount necessity of establishing a school in this country at which the tropical diseases will be taught. Dr. Manson admits that the inventive genius of the American is more likely to evolve a practical scheme for the extirpation of malaria than that of any other people. It is urged that scientific investigators, as well as men of practical experience, should discover effectual means of destroying the mosquito pest, both for the honor and in the material interests of their own people and for the sake of humanity at large.

THE PLACE OF MEETING OF THE INTERNATIONAL CONGRESS OF GYNÆCOLOGY AND OBSTETRICS.

IT has been generally supposed that the International Congress of Gynæcology would meet in London in 1902. The congress had received a unanimous invitation of the British Gynæcological Society to do so. Upon the suggestion of Dr. Engelmann, president of the American Gynæcological Society, and of Dr. Mendes de Leon, of Amsterdam, Prof. A. R. Simpson, of Edinburgh, was requested to preside, and had expressed his willingness to act in that capacity. In the mean time, however, the council of the British Gynæcological Society had communicated with the London Obstetrical Society, asking it to co-operate in a joint invitation, and received the answer that the council of the latter society deemed it inadvisable that such a course should be pursued. Dr. Engelmann then wrote to Dr. Macnaughton Jones as follows: "May I ask you again, semi-officially, as to the present state of your societies in relation to the International Congress? As a member of the International Committee, I understand that an invitation has again been extended on the part of the British Gynæcological Society. I can but repeat what I said to you in London, that I deem it most desirable that the coming meeting be held in an English-speaking country. London would be to the best interests of all interested, but I believe that I voice the sentiments of those I represent when I say that the feeling is general that the invitation could be accepted only and the congress be a success only, if the two great societies of Great Britain are united in their desire to see the congress in their midst, and I sincerely trust that some understanding has been arrived at. May I ask you unofficially if such is the case, and what is the present status?" To this letter an answer was sent to the effect that the invitation of the British Gynæcological Society had been accepted; that steps had been taken to secure the co-operation of the London Obstetrical Society, but with negative results. A committee of organization was then established with the necessary officers, at a meeting of which committee it was resolved that Dr. Macnaughton Jones be authorized to approach Professor Simpson with a view to the nomination of a London president of the obstetrical section of the 1902 congress, and that Professor Simpson be requested to communicate this resolution to Dr. W. S. Playfair. Closely following on this meeting the past and present teachers of obstetrics and gynæcology at the metropolitan medical schools met, and as a result a letter to the International Congress of Gynæcology and Obstetrics appeared in the medical journals enclosing a copy of a letter to Professor Simpson, and explaining that the objection of the signatories—who include the past and present teachers of gynæcology and obstetrics in the metropolitan medical schools now practising in London—was not to the election of Professor Simpson as president personally, but to the manner in which he was elected. In the letter to Professor Simpson himself the position taken by the London obstetricians and gynæcologists was phrased thus: "As past and present lecturers and teachers of obstetrics and gynæcology in the London medical schools, we wish to explain to you, and especially to such of our foreign colleagues as might contemplate attending such congress, that those who have issued this invitation have assumed a representative position to which they are, in our opinion, not entitled, and which we find ourselves unable to recognize." On the receipt of this communication Professor Simpson wrote to withdraw his nomination as president. The British Gynæcological Society then wrote to Dr. Jacobs, secretary to the permanent committee of the International Congress of Gynæcology and Obstetrics, explaining how matters stood, and similar letters were sent to Dr. Engelmann and Dr. Mendes de Leon. A letter was also addressed to the same medical journals which published that of the teachers of obstetrics at the metropolitan medical schools, defending the action of the British Gynæcological Society. Dr. Jacobs in his reply said that, "on the advice of a number of the founders, I think the proper course is to ask you to postpone any decision till after the meeting of the congress at Paris on August 2d."

The fact will be gathered from a perusal of the preceding résumé of the affair that matters are at a standstill, and that unless the two British societies resolve to sink their differences and come to an understanding, the International Congress is not likely to be held in London in 1902. It would be, of course, absurd to designate a body as representative of the gynæcologists and obstetricians of Great Britain which did not include the leading London specialists; but at the same time, without in the least presuming to pass an opinion upon the merits of the case, we cannot but think that it would have been wiser on the part of both societies if, rising above jealousy, they had cordially co-operated in the endeavor to make the proposed meeting in London a success, and in presenting

a united front to the world. It would seem that the action of the British Gynæcological Society in sending an invitation to the International Congress of Gynæcology to meet in London, without having been first assured of the co-operation of the London Obstetrical Society, was premature and perhaps somewhat ill-advised.

PROTECTIVE INOCULATIONS AGAINST TYPHOID FEVER.

Although the evidence is not final and conclusive, such as is accessible rather points to the utility of inoculation with sterile cultures of typhoid bacilli in the preventive treatment of typhoid fever. Thus, the official statistics with regard to the results obtained in the beleaguered military garrison at Ladysmith, as cited by Wright (*Lancet*, July 14, 1900, p. 95), show that among 10,539 non-inoculated individuals there occurred 1,489 cases of typhoid fever—a proportion of 1 : 707; with 329 deaths—a proportion of 1 : 329 of the whole number, and of 1 : 4.52 of the number of cases; while among 1,705 inoculated individuals there were 35 cases of typhoid fever—1 : 48.7; with 8 deaths —1 : 213 of the whole number, and 1 : 4.4 of the number of cases. Briefly stated, the figures demonstrate an almost sevenfold reduction in the morbidity and in the total mortality among the inoculated, with little alteration in the case mortality, but this latter fact may be in some degree dependent upon the small number of cases dealt with. It has further been reported that the disease pursued a milder course in the inoculated than in those not inoculated. There was no reason to believe that the remaining conditions to which inoculated and uninoculated were respectively exposed exerted any noteworthy influence upon the result.

News of the Week.

Saratoga County Medical Association.—A number of physicians of Saratoga county met at the Worden Hotel on September 28th, and unanimously voted to form the Saratoga County Medical Association. They organized by electing officers as follows: *President*, Dr. F. J. Sherman, of Ballston; *Vice-President*, Dr. G. F. Comstock, of Saratoga; *Secretary*, J. F. Humphrey, of Saratoga; *Treasurer*, Dr. W. E. Swan, of Saratoga. The association then formally adopted the code of ethics of the American Medical Association, and passed a resolution requesting the council of the New York State Medical Association to accept the new organization as a subordinate county association.

New York State Medical Association.—The annual meeting of this association was held in the New York Academy of Medicine on October 16th, 17th, and 18th. A very full and interesting scientific programme was provided, the chief features of which were three formal discussions, participated in by eminent physicians from this city and elsewhere. On the afternoon of the 16th there was a discussion on obstetrics, and on the evening of that day one on the blood. On the afternoon of the 17th, Prof. Victor Vaughn, of Ann Arbor, Mich., opened the discussion on tuberculosis.

J. M. Da Costa Memorial Laboratory of Clinical Medicine.—The faculty of Jefferson Medical College has recommended to the Board of Trustees the establishment of a laboratory of clinical medicine in honor of and to be named after the late distinguished Dr. J. M. Da Costa.

College of Physicians of Philadelphia—Section on General Medicine.—At a stated meeting held October 8th, Dr. A. O. J. Kelly read a paper on "Splenic Anæmia," reporting a case. Drs. M. H. Fussell and J. D. Steele presented a report of two cases in which the signs of mitral stenosis disappeared as cardiac compensation was re-established.

Large Bequest to a Hospital.—By the will of the late Charles Edward Orme, of Philadelphia, an estate of $50,000 is devised to the Episcopal Hospital, to maintain as many free beds, to be known as the "Charles Edward Orme Free Beds," as the income will support, after the death or remarriage of the widow.

University of Pennsylvania.—It has been announced unofficially that the wife of Dr. S. Weir Mitchell will present to the University of Pennsylvania, in memory of her daughter, either an addition to the present hospital building or a separate structure for the treatment of those suffering from contagious disease.

Medico-Chirurgical College of Philadelphia.—Hon. Edward M. Parson, ex-chief justice of the supreme court of Pennsylvania, has been elected president of the Medico-Chirurgical College of Philadelphia. It is expected that the nine representatives of the faculty and the one representative of the Alumni Association on the board of trustees will withdraw, so that the board shall be constituted of fifteen laymen.

Pathological Society of Philadelphia.—At the annual meeting held October 11th, the president, Dr. F. A. Packard, read the annual address; the treasurer, Dr. T. S. Westcott, made his report for the year; and the following officers were elected: *President*, Dr. F. A. Packard; *Vice-Presidents*, Drs. Joseph McFarland, C. W. Burr, Alfred Stinzel, Simon Flexner; *Secretary*, Dr. J. Dutton Steele; *Treasurer*, Dr. Thompson S. Westcott; *Curator*, Dr. W. Wayne Babcock.

Typhoid Fever at Newport.—Quite an epidemic of this disease exists at Newport, R. I., and it is reported that there are over fifty cases in the city. The hospital accommodations are overtaxed, and the board of alderman has appointed a committee to arrange for the establishment of an emergency hospital. Newport has no regular board of health composed of medical men or sanitarians, the aldermen acting in that capacity, and on this account it is much harder to deal with such cases.

The Hospital Ship "Maine."—The American ladies' committee in London has received a cable despatch from Wei-hai-Wei, China, dated Wednesday, October 10th, reporting the return there of the American hospital ship *Maine* from Taku with many invalids on board, of whom two officers and sixty-nine men are Americans. Eighteen of the latter belong to the Ninth Infantry. The *Maine* sailed for Nagasaki on October 11th.

The Psychological Laboratory at Columbia.—Many improvements in this laboratory, made possible by a gift of $100,000 from Mr. John D. Rockefeller, have now been completed, and the space and facilities of the department have been materially increased. The new arrangement gives Columbia facilities for psychological work that are said to be unequalled by those of any university, with the possible exception of that of Leipsic.

Health Conditions in Guam.—Surgeon-General Van Reypen of the navy does not approve of Guam as a naval station, his objection being based upon sanitary grounds. In his annual report to the secretary of the navy he says that typhoid fever is practically endemic in the island, owing to the pollution of drinking-water in shallow wells near cesspools and to the very common lack of any provision whatever for the receipt of refuse matter. The disease appeared among the United States sailors soon after their arrival on the station, as access to contaminated water was under the circumstances unavoidable. During less than five months there were twenty-five cases and four deaths from this cause in a force of one hundred and forty-three men. The climate, he says, is debilitating after a protracted residence, but is not in the main bad. The mean annual temperature is above 77° F., but in the winter months, though the days are hot from the larger amount of sunshine, the nights are sufficiently cool for blankets. At this season the humidity is lessened. From June to November or December the rainfall is heavy and almost constant, but during the rest of the year the climate is very agreeable. Leprosy is not common and the disease is not increasing. There are only fourteen cases known to be on the island at this time. The surgeon-general thinks it would be better to establish a station on Cabras Island, which is uninhabited and consequently uncontaminated, in place of the present one at Agana. As Cabras Island is not inhabited, its soil is free from infection. Its natural drainage is excellent, and it is reported that there is at hand an ample supply of potable water.

Yellow Fever.—One hundred and thirteen new cases of yellow fever were reported in Havana during the first twelve days of October. During September there were fifty-two deaths from yellow fever in that city. There were sixty-four cases among Americans and one hundred and eighty-six among Spaniards. Of the former five died and of the latter thirty-seven. The Americans there say that now is the time to have the disease, when the cases are working out a low death rate. The average death rate is 25.68. This is considerably better than for any September in the last ten years with the exception of that month last year. The health authorities under Major Gorgas are making six hundred house inspections daily, with a view of enforcing cleanliness. In a recent interview, Governor-General Wood is reported to have expressed the belief that the disease is propagated by means of bites of insects, either fleas or mosquitos. This is the theory long since promulgated by Dr. Carlos Finlay, of Havana, but which found little support until the agency of mosquitos in the spread of malaria became an established fact. Yellow fever is epidemic at Vera Cruz and other ports on the lower Gulf coast of Mexico, but Tampico is declared free, there having been but two cases there this summer. A report that the disease had made its appearance at Monterey has been officially denied.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended October 12, 1900:

		Cases.	Deaths.
Smallpox—United States.			
Alaska, Nome	October 7th	1*	
Kansas, Wichita	September 29th to October 6th	1	
Ohio, Cleveland	September 29th to October 6th	10	
Pennsylvania, Philadelphia	September 29th to October 6th	4	
* In barracks.			
Smallpox—Foreign.			
Austria, Prague	September 8th to 15th	1	
Brazil, Pernambuco	August 24th to 31st	..	4
England, Liverpool	September 15th to 22d	1	
London	September 15th to 22d	2	
France, Paris	September 15th to 22d	..	3
St. Etienne	September 1st to 15th	1	1
Germany, Konigsberg	September 8th to 15th	2	
Mexico, Vera Cruz	September 22d to 29th	..	1
Russia, Odessa	September 15th to 22d	11	2
St. Petersburg	September 8th to 15th	9	5
Scotland, Glasgow	September 21st to 28th	22	3
Yukon Territory, Dawson	September 8th	Present.	
Yellow Fever.			
Colombia, Barranquilla	September 16th to 23d	..	1
Cartagena	September 1st to 14th	3	3
Cuba, Havana	September 22d to 29th	..	19
Mexico, Vera Cruz	September 22d to 29th	..	10
Plague.			
Paraguay, Asuncion	July 21st to 28th	..	2
Scotland, Glasgow	September 15th to 22d	3	2
Wales, Llandoff	October 5th	..	1*
* Imported from Rosario.			
Cholera.			
Straits Settlements, Singapore	August 11th to 25th	..	1

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending October 13, 1900. October 8th.—Passed Assistant Surgeon T. W. Richards detached from the *Indiana* and ordered to the *Alabama*, October 16th. October 9th.—Passed Assistant Surgeon L. Morris ordered to the naval academy. Assistant Surgeon D. H. Morgan detached from the *Vermont* and ordered to the Pensacola navy yard. Assistant Surgeon J. A. Murphy detached from the Pensacola navy yard and ordered to the Asiatic station for duty on the *Don Juan de Austria;* to report at San Francisco, Cal., October 30th, for passage on the *Solace*. October 10th.—Assistant Surgeon H. H. Haas detached from the *Don Juan de Austria* and ordered home and to wait orders. October 12th.—(Orders issued by commander-in-chief of Asiatic station.) Passed Assistant Surgeon G. A. Lung detached from the *Monocacy* and ordered to the

Cavite naval station. Assistant Surgeon J. C. Thompson, detached from the *Monocacy* and ordered to the Cavite naval station.

The Plague.—An official bulletin has been issued in Glasgow announcing that the outbreak of plague in that city has been completely checked. All the suspects have been released, and the reception houses were closed on October 11th. On that date twenty convalescents were still in hospital. When the bubonic plague appeared in Glasgow, Dr. A. H. Doty, health officer of the port of New York, ordered a quantity of plague serum from the Pasteur Institute, at Paris, as a precautionary measure for use at quarantine in the event of the plague being brought to this country by a steamer from the infected port. The serum arrived some days ago, and is now in the quarantine laboratory.

Obituary Notes.—Dr. Crawford Irwin died at Hollidaysburg, Pa., on October 7th, at the age of seventy-six years. He was president of the Medical Society of the State of Pennsylvania in 1875 and 1876.

Dr. Jacob P. Russel died at Philadelphia on October 7th, at the age of sixty-four years. He was graduated from the Medico-Chirurgical College in 1887.

Dr. William M. Caterson died at Philadelphia on October 7th, at the age of seventy years. He was a graduate of Jefferson Medical College.

Dr. Ross Richardson Bunting died at Philadelphia on October 10th, at the age of sixty-six years. He was a graduate of Jefferson Medical College and of the École de Médecine of the University of Paris.

Dr. Joseph L. Cutler died at his home in Bolivar, N. Y., on October 14th, at the age of seventy-one years. He was born in Moravia, N. Y., graduated from the University of New York in 1850, and the same year located in Bolivar. He served ten months as assistant surgeon of the One Hundred and Thirty-fourth Regiment New York Infantry during the Civil War.

Dr. Franklin Smith, seventy-six years old, died at his home in this city on October 9th, after a short illness. He was born in this State, and for over a quarter of a century had been a resident of this city. He was a graduate of the Medical Department of the New York University in 1865. He was a member of the Medical Society of the County of New York. Three daughters and one son, Dr. Charles Smith of this city, survive him.

Dr. Benjamin Hussey West, one of the old graduates of Harvard University, died at Neponset, Mass., on October 11th. He was born in Nantucket, November 10, 1814, and was the son of Paul West, a lieutenant in the British navy and commander of the ship *Cyrus*. He graduated from Harvard in 1835 in the class with the late Bishop Williams of Connecticut, Judge E. R. Hoar, Amos A. Lawrence, John A. King, and others who have been prominent in public life. Only five survivors of the class remain. He was graduated from the Harvard Medical School in 1838 and commenced professional life at Pawtucket. In the early forties he went to California, where he remained for several years, being a member of the committee of safety during 1849. Later he was for many years head surgeon of the Pacific Mail Steamship Company.

Progress of Medical Science.

New York Medical Journal, October 13, 1900.

The Future of Specialties.—In a general consideration of the relationship of post-graduate instruction to special work in medicine and surgery, C. B. Kelsey says: "The advice of every specialist to those who are desirous of coming into his special field, no matter what his own course may be, is invariably now: fit yourself for a surgical specialty by first learning general surgery. The result will be that a man who has once studied general surgery will never be a narrow specialist. Some one branch of work he may prefer, and that branch may in time come to him to the exclusion of others; but arbitrary lines will not limit him so closely as they have done in the past. We can all remember when gynæcology consisted practically of plastic work upon the uterus and vagina. It will never go back to it. The specialty to which I have devoted my own life is still thought by many to consist properly of piles and fistulæ, but it will never again be separated from gynæcology and genito-urinary surgery. Since, for success in any specialty, a broader education will be necessary, this will be acquired before special work is begun. There will be fewer men who have begun as specialists and have never done general practice, or men will commence special practice after more years of preparation. But specialists will not disappear, for the very same reason that they ever came into existence, which is that the whole field of medicine is too large to be covered by any one man, no matter how hard the exigencies of life may induce him to try; and those who have devoted the most study to any one field and acquired the greatest experience in it will always be sought after by the public to practise in that field."

Dilatation of the Colon.—H. G. Marxmiller gives the following clinical history of a case and illustrates his paper with some excellent photographs. He regards the condition as undoubtedly secondary to a tertiary lesion of the spinal cord, which at last accounts was responding slowly to specific treatment. His patient was a machinist aged fifty-two years, a man of medium build. He had contracted syphilis twenty years before, for which he had received treatment. Ten years after the initial lesion had appeared, several specific leg ulcers were observed. He had been apparently well up to three years ago, when, while working in a machine shop on a cold November day, he was seized with an attack of chills accompanied by fever. There was also severe pain in the dorsal region, which by morning had become inflamed. There was no suppuration or necrosis. Ten days after the acute symptoms had subsided, a marked angular curvature of the spine was observed, and a week later dilatation of the colon.

On the Employment of the Upright Position in Ether Operations upon the Nose, Throat, and Ear.—By means of some excellent photographs T. R. French illustrates his method, which consists in bringing the patient partially under the anæsthetic, as usual, and then placing him in the specially devised chair used, and gradually bringing the latter from a position of being tilted far back to an upright position, the patient being fastened to the chair. By the time the upright position is reached the patient is sufficiently under the anæsthetic for the operation to begin. No bad results have been experienced, and French claims for the upright position the threefold advantage of reduction in amount of blood lost, better nasopharyngeal drainage thereby lessening the liability to ear complications, and finally the ease, thoroughness, and accuracy with which operations can be done in the shortest time by the retention of the usual relationship between operator and patient.

Hypertrophy of the Turbinated Bodies and their Relations to Inflammation of the Middle Ear, with a Report of 1,500 Operations.—By C. R. Holmes.

The Present State of Our Knowledge Concerning the Cause, Nature, and Treatment of Asthma.—By W. A. Wells.

The Etiology of Pulmonary Tuberculosis, its Course and Termination.—By S. A. Knopf.

Boston Medical and Surgical Journal, October 11, 1900.

Breast Feeding.—A. Worcester says that both for the mothers' sakes and the babies' sakes physicians are in duty bound to urge the vital importance and the otherwise

unattainable advantages of breast feeding. Much to this end can be done during pregnancy in teaching women what to expect. When the baby is first put to the breast, the physician's largest chance of service comes in. His unstinted time and patience are then needed. Nature's indications should be followed, and the child not stuffed with food in the first three days of life. It will then be hungry enough to ease the aching breasts when there is a supply of milk. No washes are to be used on the nipples, but olive oil or lanolin, with tallow and beeswax, or the raw white of egg for a protective dressing. Cracks and excoriations will then be infrequent. If they occur, disinfection with a boracic-acid lotion (five per cent.) should be followed by anæsthetizing with cocaine and treatment with a ten-per-cent. solution of silver nitrate. The part is then dried by pressure of absorbent cotton and painted over with egg albumen. For the next few nursings a glass-bell nipple shield should be used.

Home Modification of Milk.—Charles W. Townsend thus concludes his article: The modification of cow's milk, with a knowledge of the percentages, is preferable to guesswork feeding of infants. Percentage feeding can be carried out by a milk laboratory or by home modifications. Milk laboratories are unavailable to many, and, in the experience of the writer, do not agree with infants as often as home modifications. Laboratory modifications are necessarily subjected to more handling and transportation than home modifications. Milk that is fresh, clean, and from cows free from tuberculosis is preferable uncooked, or, in other words, pasteurization and sterilization, although sometimes essential, are to be avoided if possible. The method of home modification and of calculating percentages should and can be made extremely simple, and such modifications are sufficiently accurate and uniform. The addition of cereals to the milk in the form of barley or oatmeal water is generally advisable after the seventh month, and is desirable before that age in some cases as an aid to the digestibility of the milk.

Lesion of the Chiasm.—S. A. Lord reports a case of this disease occurring in a laboring man aged thirty-two years, born of consanguineous parents, with a family history of gigantism and neuropsychopathic tendencies, this individual himself presenting evidences of gigantism and signs of degeneracy, and of defective development. There is no doubt of the existence of a chiasm lesion, the trouble having first involved the fasciculi of the left optic nerve, and subsequently, in succession, the fasciculus cruciatus and fasciculus lateralis of the right. The presence of a tumor is rendered probable by the facts that other conditions causing these visual symptoms can be eliminated, that the headache, vertigo, tinnitus, and momentary loss of speech, and the irritative optic-nerve symptoms can be better explained as tumor symptoms than otherwise. There is at least one focal sign, slight in itself, but extremely suggestive of tumor—strabismus. Various arguments point to the probability of a tumor of the hypophysis.

The Modification of Milk in Milk Laboratories.—By T. M. Rotch.

Philadelphia Medical Journal, October 13, 1900.

General Summary of the Cases of Typhoid Fever Treated in the Johns Hopkins Hospital for Ten Years.—William Osler makes the following report of the 829 cases of typhoid fever which have been under his care or that of his assistants to May 5, 1899: Sex—631 were males; 198, females. Race—729 were white; 100, colored. As to nationality the Americans predominated, numbering 348, Germans, 200; the remaining number being Irish, Bohemians, English, Poles, etc. Age—393 were between twenty and thirty years of age, the largest number in any one decennary. Mortality—7.5 per cent., there being 63 deaths in the 829 cases. Treatment: (1) A careful and thorough system of nursing; (2) diet, milk diluted with limewater and egg albumen form the standard diet of the febrile stage; abundance of cold water; (3) hydrotherapy, either the full tub at 70° F., or, if occasion requires, ice-cold sponges; (4) drugs: as a rule no medicines are given. If the pulse becomes rapid and feeble, he gives alcohol in the form of good whiskey, and strychnine, if necessary, in full doses. No antipyretics and no intestinal disinfectants are to be given. Special complications require and receive appropriate treatment. The rash—Rose-spots were present in 666 cases. Diarrhœa—There was diarrhœa at the onset in 322 cases before the patient entered the hospital. In 163 of the 829 cases, *i.e.*, nineteen per cent., there was diarrhœa at some time or other in the course of the disease, and in 290 cases, thirty-four per cent., there was constipation. Relapse—We are still really without full knowledge of the causes of relapse, but the frequent occurrence is a positive indication that immunity in typhoid fever is slowly acquired, and not reached at the period of apyrexia. There were 86 relapses, a little more than ten per cent. Under complications and sequelæ are mentioned hemorrhage from the bowels, perforation, hæmatemesis, phlebitis, pneumonia, albuminuria, tube casts, acute nephritis, orchitis, and herpes.

Concerning Calentura.—Frank W. Foxworthy states that in tropical countries the term "calentura" embraces anything from pernicious malarial fever to a simple pyrexia, and the natives often designate any febrile condition as calentura. It should, however, be strictly limited to that fever occurring usually during the months of December, January, and February, which exhibits the symptoms of a simple continued fever with a small mortality. There is generally a sudden rise in temperature to 104°, 105°, or even to 106° F., with headache, malaise, furred tongue, anorexia, pains in the back, chest, and legs. The differential diagnosis from dengue is difficult. But the terminal fever and the ever-present eruption and desquamation of dengue are entirely absent. Variola, however, with its high initial fever and the sharp lumbar pains, also is much like calentura. Typhoid fever will not be diagnosed in a case of calentura, on account of the temperature chart, absence of epistaxis in calentura, absence of abdominal pain and borborygmus and of the typhoid eruption. Phenacetin or antipyrin in large doses seem specific. Cool baths are given. The fever is rarely fatal in the Philippines. Whether ths fever will be designated as one of the obscure varieties of malarial fever, or will be known as a distant relation of "influenza," which it simulates often in epidemic form, or whether it will continue to be one of the many unclassed fevers of the tropics with only a local appellation, time and the microscope will decide.

A Consideration of Finger Infection with Special Reference to the Joints and Tendons.—Ellsworth Eliot, Jr., at the close of his paper on this subject cites several cases, one of which especially is of unusual interest. It is that of a man aged thirty-two years, in the palmar surface of whose right middle finger, over the junction of the first and second phalanges, a small fragment of glass became embedded. This the patient removed with an old razor, and several hours later there were unmistakable signs of infection. Infection was introduced a short distance only beneath the skin, and from this point, notwithstanding early and extensive incisions, the infecting material was carried not only into the tendon sheath, but also into the joint. The separation of necrotic tendon required several weeks longer than usually is the case; in fact, at one time it was hoped that notwithstanding the suppurative tenosynovitis the viability of the tendon might be preserved. The arthritis behaved in a very peculiar way. The second phalanx was double its normal size and denuded through a considerable part of its extent. Yet exfoliation did not take place *en masse*, although that there must have been some gradual loss of bone is demonstrated by the permanent shortening of the finger. The thickened condition of the phalanx persisted months after healing was complete. The occurrence of secondary hemorrhage was an indication merely of insufficient drainage of the abscess cavity. This demanded the joining together of the incisions on the anterior aspect of the finger and lower palm of the hand—a procedure which is usually necessary before the abscess cavity will heal. In the majority of cases of joint infections a stiff finger results which greatly impairs its future utility, even if the finger is not actually in the patient's way. In these cases the question of amputation is one for the patient, not the surgeon, to decide.

The Prevention and Treatment of "Colds."—W. Scheppegrell declares that coryza is of such frequent occurrence and plays so important a rôle in the development of other affections, that the subject merits the most careful attention, especially as the most diverse opinions exist as to its etiology and treatment. Prophylaxis is of the first importance. Overheated rooms should be avoided. The clothing should not be too heavy or warm. The cold shower bath is an excellent preventive. The nasal passages should be kept in normal condition. The writer affirms that his personal experience and observation have convinced him that there are but few constitutional remedies of any value in this condition. When coryza is due to a uric-acid diathesis lithia is sometimes effective. Un-iced water is also beneficial. A brisk saline purgative within the first twenty-four hours is most useful. Cocaine should

rarely be used and never be prescribed. It has enormous possibilities for evil. The nostrils may be bathed with a warm one-half-per-cent. salt solution. It should be applied by some sort of douche, gently, and the nose should not be blown for ten or twenty minutes. When the general condition is kept in good trim, coryza will be very infrequent.

Cocaine Anæsthesia by Lumbar Puncture: Two Cases of Hysterectomy.—J. Riddle Goffe writes that the success which has attended the intraspinal injections of cocaine for producing anæsthesia was considered one of the prominent advances in surgery at the recent International Medical Congress. The credit of demonstrating the advantages of this method is due to Professor Bier, of Kiel, but Tuffier, of Paris, and Kreis, of Bucharest, have used it in a greater number and a wider variety of cases. So far, no detriment to the patient has attended the procedure; complete analgesia is produced during operations extending over a period of two hours, the benumbing effect gradually wearing off in three or four hours, as a rule. The amount of the drug used varies from gr. 1½ to ½. The analgesic effect extends usually from the toes to the umbilicus, and operations may be performed with immunity to pain on any parts below the latter point. The writer then describes his two cases, one of which was a vaginal hysterectomy, the other an abdominal hysterectomy. The results were most favorable.

Treatment of Rheumatism and Some Phases of Indigestion; Gouty Diathesis.—By Charles E. Page.

Journal of the American Medical Ass'n, Oct. 13, 1900.

A Study of the Inoculation Theory of Malarial Fever.—Albert Woldert states that one may devise either of two methods in studying the relation of mosquitos to malarial fever; first to search for the anopheles in its native haunts, and then for the case of malarial fever; or secondly, to find the case of malarial fever and afterward look for the anopheles. According to observations made by different scientists in various parts of the world, it has been demonstrated that not all genera of mosquitos are capable of inoculating man or birds with malarial fever. This power so to do appears to rest solely with the different species of the genus anopheles. Studies of the human blood reveal the presence of certain small, round, actively motile intracorpuscular organisms. These grow to full development at the expense of the red blood disc, and subsequently rupture, setting free a number of hyaline bodies that at once re-enter other erythrocytes. These results therefore go to show that the sporozoa or plasmodia of Laveran require for their complete existence two biological cycles, one being completed in the body of man, the other being completed in the tissues of the mosquito. Should the mosquito be the only agent in disseminating malarial fever, the destruction of the larvæ or pupæ of that insect would be only one way of getting rid of the disease. Manson suggests the following methods: (1) To begin by administering quinine for long intervals in all cases of malarial fever, since a single man is a source of infection to a whole locality; (2) to cause all persons suffering with malarial fever to sleep under mosquito netting; (3) to compel all the uninfected to sleep in mosquito-proof houses or beds; (4) to kill by different culicicides all mosquitos entering houses; (5) to destroy all the mosquito larvæ before they reach maturity or the biting stage—to which might be added the destruction of the adult mosquitos in their places of hibernation; (6) the combination of all these methods."

The Atrophic Pharynx.—Ralph W. Seiss writes that all types of simple chronic inflammation of the pharynx tend to progress into the atrophic form. What might be called the average type of chronic pharyngitis is characterized by the enlargement of the lymph glands, giving the so-called follicles, by dilatation of the superficial blood-vessels, and especially by the formation of small masses of granulation tissue, which are usually situated immediately behind the posterior half arches of the palate. Atrophic areas, showing as sunken, glistening, light-colored spots, occur in the central portions of the pharyngeal wall. Such a throat may remain *in statu quo* for half a lifetime, but in certain cases the greater portion of the pharyngeal surface is infiltrated. The pathological process is identical with fibrosis elsewhere. The etiology is almost unknown. Gouty subjects are more prone to it than others. Treatment so far as restoring function is concerned must always be unsatisfactory. Stimulant and alterative sprays, such as oil solutions of gaultheria, cinnamon, thymol, and the like, are certainly of benefit. The physician should apply them, and only to a membrane which has been carefully cleansed by an alkaline spray. The massage effect of properly chosen atomized fluids when driven with a pressure of from fifteen to eighteen pounds is very decided and most beneficial. In the irritable cases much less can be done. Pigments seem to give more definite results than nebulæ. Thymol solution in alcohol and glycerin, tincture of sanguinaria and glycerin and copper sulphate, are favorites with the writer; iodine is sometimes useful. Too much must not be hoped for, and patients must be frankly told that the condition is not definitely curable.

Systematic Cleansing of the Nasal Cavities before Operations which Involve Opening of Eyeball.—J. A. Lippincott describes his method as follows: A few hours before operation in every case, a spray of potassium permanganate, 1:2,000, is thoroughly applied to the nostrils. In some cases the spraying is repeated immediately before the operation, and when there is decided evidence of nasal disease each of the three or four days succeeding it. The permanganate spray has potency enough to destroy a large proportion of the organisms with which it comes in contact. This procedure has been carried out in one hundred and fifty-two operations in which the globe was penetrated, and there was not only a complete absence of any sign of suppurative inflammation, but there was an unusual degree of freedom from inflammation or irritation of any kind, although a number of the cases were of an unfavorable nature. The wounds healed with less than the usual degree of redness, and convalescence was more speedy than in previous experiences.

Cellulitis Succeeding Contusion of Leg; Extensive Sloughing; Skin Grafting; Recovery.—Henry W. Sawtelle reports this case. The lesion occurred in a Danish seaman aged twenty-four years. He was struck on the inner side of the left leg by a piece of lumber, apparently only a slight contusion resulting. Chill, fever, and intense headache followed in a few hours. The injected area in the leg was incised, evacuating much pus. Two days later a second incision was made. Sloughing followed, despite careful antiseptic treatment. As soon as the wound allowed, skin grafting was performed with happy results. The lowered condition of the constitution probably accounted for the history of the infection.

Epithelioma.—Charles J. Whalen reports two cases, the first that of a man aged eighty-five years, who was afflicted by this growth for twenty-one years before he died. The second case was of a man aged forty years. The writer removed this growth, which was on the right side of the nose just at the point where the nose-rest of the glasses rests. Nearly four years later the patient was enjoying the best health. These seeming warts and dry fissures in people past middle life are always suspicious.

The Lancet, October 6, 1900.

Aneurism of the Renal Artery.—H. Morris regards aneurisms at this site as among the very rare lesions seen in the human subject. Two varieties may be found after injuries: (1) Small sacciform aneurism, the walls of which are formed by some or all the coats of the artery; and (2) large, false aneurism, the walls of which are composed of the condensed fibrous tissue developed around the extravasated and coagulated blood, and with which the surrounding organs and tissues become more or less firmly matted. The latter may develop in three ways: (1) By the giving way of a small, true aneurism, which may be either of spontaneous or traumatic origin; (2) by the yielding of a thrombus which temporarily closed a ruptured artery; and (3) by the immediate outpouring of blood from a ruptured artery. From the analysis of quite a large number of cases he summarizes the symptoms as tumor, and contrary to the usual rule in this affection without pulsation, a possible bruit, pain, and hæmaturia, with such constitutional symptoms as might be expected from loss of blood and pressure. The urine, except for the blood and a little albumin between the attacks of bleeding, is normal. The only treatment offering any satisfactory result is nephrectomy and the removal of all or a part of the aneurismal swelling.

The Limits of the Heart Dulness in Cases of Anæmia and Chlorosis.—R. Wybauw says that if the cardiac muscle loses its strength because its nutrition is impaired, contraction will become impossible and dilatation will occur. This condition arises when the relation between the pressure of the blood, especially in the ventricle, and the strength of the muscle is no longer normal, the latter being unequal to the former. It may be that in chlorosis there is

a general infiltration of the tissues by effused blood serum. The heart muscle would be affected the same as other muscles and cause a diminution of force leading to dilatation. As the quality of the blood is improved by appropriate treatment, this effusion is gradually lessened and the force of the cardiac muscle increased with a consequent return to normal conditions. Illustrative cases are given.

A Case of Acute Albuminuria (Acute Renal Congestion) with Uræmia; Recovery.—The case is reported by F. C. Evill, and is of interest in view of the extremely short period elapsing (three days) between the patient's being in perfect health and his passing through the usual renal symptoms into a distinctly uræmic condition with restlessness and a convulsion. No unusual symptoms in kind were noted. Great relief followed free venesection at the critical period of the attack, and oxygen was administered with much benefit. The patient made a good recovery. S. West, who saw the case in consultation, adds notes of two similar cases from his own practice.

A Case of Anthrax.—Reported by E. F. M. Neave. The source of infection was bone dust which the patient had handled. He died on the fourth day after his initial symptom. The temperature did not rise above 100° F. The lesion was situated on the breast where he had scratched himself, and there was an entire absence of pain, severe constitutional disturbance, and feeling of distress.

Address on Science and Practice.—By G. V. Poore.

British Medical Journal, October 6, 1900.

An Address on Some Problems of Tropical Medicine.—Sir William MacGregor in his address touches on the following diseases: Sporadic cases of typhoid fever have been met with in Polynesia since 1875, but there is a form of continued fever which simulates typhoid up to the ninth day, when it culminates suddenly and the patient recovers in a few days. The disease of yaws has been from time immemorial endemic in Polynesia. It is, like most other diseases in the torrid zone, parasitic. Venereal disease was not known to the Pacific Islanders nor to the Papuans till taken to them by Europeans. In the islanders the soft chancre often developed into a great spongy mass, easily bleeding. Sometimes the ulcer penetrated the abdominal wall. Syphilis was slower in its processes. Gonorrhœa was all but incurable in native women. Measles was introduced into Fiji by one of Her Majesty's ships of war. The epidemic which followed destroyed between one-third and one-fourth of the whole population. The itch in British New Guinea also spread like wildfire at first in its most virulent form. Dysentery in its epidemic and contagious forms was unknown in British New Guinea ten years ago. In recent years it has caused many deaths there. It probably causes more deaths than any other disease in tropical countries. No other malady is so universally distributed and of such constant occurrence. To the tropical European, the most important study is probably that of malarial fever. The parasitic cycle in malarial fever is undoubtedly proved by demonstration. Now we require to know how and why certain conditions bring on an access of fever long after possible infection and in spite of long-continued and large doses of quinine. Koch is convinced that a practical inoculation against Texas fever can be arrived at. Elephantiasis is very common in Fiji. There seems to be no connection between this disease and malaria as some have supposed. Phthisis was not known to the Papuan. The natives of New Guinea are, however, very subject to a form of pleuro-pneumonia. The first case of diphtheria that occurred in Fiji was about twenty years ago. The disease was brought from Sydney. Lupus exedens is very common in New Guinea, but it is always clearly distinct from cancer. Tetanus has been known in British New Guinea. Tinea imbricata has made a steady, stealthy progress. Ankylostomiasis is indigenous in the Pacific. In New Guinea there is a curious multiple tumor as large as a walnut which is met with. It is probably parasitic, but has not been investigated. The Australian and New Guinea dingoes are free from rabies. The "jigger" should be carefully studied. The whole subject of leprosy requires to be studied exhaustively in the light of the new pathology. The quarantine is necessary in the colonies. The author then emphasizes the importance of becoming expert in the examination of water.

The Causes and Treatment of Non-Malignant Stricture of the Rectum.—Frederick Charles Wallis believes the most common cause of rectal stricture to be septic ulceration, primarily started either by some septic discharge from the outside, attacking an abraded portion of the mucous membrane, or post-operative sepsis. Protracted labor is another cause. Patients suffering from rectal ulceration are apt to have attacks of acute synovitis. The author describes his operative measures in two cases, the latter of which is as follows: A primary inguinal colotomy was performed. Some months later the rectal operation was performed. The patient being placed in the lithotomy position, the sphincters were stretched as much as possible. An incision was then made all round the anus at the muco-cutaneous margin, and the mucous membrane gradually separated from the sphincter by scissors, and the separation continued right up to the stricture. Great care had to be exercised at this point, but after the stricture had once been passed the mucous membrane was quite healthy. The peritoneal cavity was opened on both sides, particularly on the right; these openings were closed again by sutures. The bowel was divided above the stricture through healthy mucous membrane, and the lower parts with the stricture were removed; the cut edges of the healthy bowel were brought down to the skin margin by gentle traction and sewed to it by a large number of interrupted sutures of chromicized catgut. No vessels were ligatured. The subsequent course of this operation was uneventful. A few weeks later the colotomy wound was closed. The patient is now in the best of health.

On the Best Method of Removing Large Stones from the Bladder: with Notes of a Case.—S. H. Burton states that the advantages of suprapubic lithotomy are that the bladder can be opened freely and examined fully, in an almost bloodless manner, and a stone of any known size extracted with least disturbance to the patient of any operation, and in the case of enlarged prostate these advantages are accentuated. The disadvantages are that the wound may be long in healing, and sometimes phosphates may crust on the scar, reproducing another stone. The advantages of perineal lithotrity are that the bladder wall is not cut, and the neck of the bladder is incised only enough to admit the finger, and afterward the lithoclast, and the opening into the bladder is dependent. The disadvantages are many: frequent instrumentation during the operation; disturbance of the neck of the bladder by removal of stone fragments; the bruising of the vesical mucous membrane by the lithoclast when the bladder is contracted around a large stone; the impossibility of examining the bladder with the finger in the case of a big man with a deep pelvis, and the difficulty, when there is a large prostate, of manipulating the instrument easily, and of removing all the fragments, and lastly when the kidneys and ureters are diseased, owing to chronic dilating and infective changes, the danger of setting up acute pyelitis and nephritis is increased in proportion to the manipulation. The author believes the suprapubic operation to be the best one for large stones.

A Case of Obstructive Jaundice due to Gummatous Infiltration, Involving the Head of the Pancreas, Duodenum, and Gastro-Hepatic Omentum, in which Cholecystocolostomy was Performed with Complete Cure.—H. Betham Robinson reports this case, in which he performed an exploratory laparotomy, draining the gall bladder. Potassium iodide was ordered, and the further history was most satisfactory. The progress of the case after the operation leaves little doubt that the lesion causing the jaundice was an extensive gummatous infiltration radiating from the head of the pancreas. Such a manifestation of visceral syphilis must be extremely rare, and hence unsuspected. The length of time during which the improvement continued, with the marked increase of weight, are conditions which cannot be accounted for by the laparotomy alone, or from the relief of the bile obstruction.

The Etiology of Phlyctenular Affections of the Eye.—Sydney Stephenson regards phlyctenular disease, generally speaking, as due remotely to the tuberculous diathesis, and immediately to an eruption of eczema upon the surface of the eyeball. Anything tending to lower general resistance, as measles or imperfect hygienic surroundings, or local resistance, as slight injuries to the eyeball, may induce the disease in a predisposed subject. It is important to bear in mind that eczematous inflammations may involve mucous membranes other than the conjunctiva, and that such changes when found may help to elucidate the etiology of an otherwise obscure corneal ulcer.

A Discussion on Subdiaphragmatic Abscess.—By Rickman J. Godlee.

The Huxley Lecture.—By Lord Lister.

Berliner klinische Wochenschrift, September 17, 1900.

A Case of Chronic Diffuse Œdema of the Skin.—H. Rosin reports the case of a woman aged forty-two years, presenting swelling of the face, upper portion of the chest, backs of the hands, and knuckles. It came on without apparent cause and did not seem to be associated with any internal disturbance. The skin was not so stretched that it could not be lifted up in folds. The thyroid was not enlarged. No history of any exanthem could be obtained. There were no glandular enlargements, no fever or sensory disturbances. The pulse was normal. Differentiation was called for between erysipelas, myxœdema, Graves' disease, scleroderma, and nephritis; but all these could be excluded. The condition was regarded as due to some disturbance of the circulatory apparatus taking the form of an abnormal permeability of the vessel walls. The condition of the patient was stationary when the report was made.

An Additional Case of Polyneuritis following Malaria.—C. A. Ewald's patient was a man aged thirty-one years, who suffered from what was regarded as a malarial attack, though no organisms were found in the blood. On admission to hospital, he showed a paresis of the lower extremities, while the patellar, skin, and periosteal reflexes were completely lost. His gait was weak, and he had to be supported, but showed no typical ataxia. The speech was rather stumbling, and he found it difficult to continue conversation, as his mind seemed blunted. Electrical reactions were normal for both currents. The spleen was large, urine normal. The case was regarded as a form of polyneuritis due to malarial infection.

Polyneuritis after Malaria and Landry's Paralysis.—In this article R. Baumstark reviews the literature of the conditions named in the title and discusses the differential diagnosis of the two diseases.

Doubling of the Left Index Finger and a Threefold Division of the Right Thumb.—By Dr. Joachimsthal.

A Metrical Visual Disturbance in Hemianopsia.—By H. Liepman and E. Kalmus.

Deutsche medicinische Wochenschrift, Sept. 27, 1900.

Observations on a Case of Multiple Typhoid Periostitis.—Conradi discusses the interesting question of how much significance attaches to the presence or absence of the Gruber-Widal reaction in determining the nature of post-typhoid suppurations, especially those involving the bones. In a case observed by the author five months after a typhoid infection, which ran its usual course, the bacillus typhosus was isolated and cultivated from pus obtained from periosteal lesions in several parts of the body, and its specificity and virulence were positively determined. A positive Widal reaction, however, was not to be obtained from the blood serum, and this observation leads the author to several noteworthy conclusions. The first of these is that in metastatic typhoid lesions the agglutination reaction is not to be relied on as an index of the origin of the trouble. The conditions which make it possible for the bacillus to maintain its vitality in remote portions of the organism, after the disease has run its course and the body is supposably thoroughly charged with immunizing bodies, afford a rife topic for speculation. It is well established that the bone marrow participates in every typhoid infection as constantly as do the spleen and intestine; how is it, then, that it is only the latter two that are able completely to dispossess the invaders, in spite of the fact that the bone marrow itself is one of the most prolific sources for the manufacture of the anti-typhoid protective substances? Furthermore, why are not other tissues also attacked? We must take it for granted that owing to its reactive changes the body has become at least an unfavorable dwelling-place for the bacillus, and that in order to keep its foothold it must greatly adapt itself to the new conditions, and so parts with a large measure of its virulence, becoming locally active only when the system is again invalidated by exterior conditions, other infections, trauma, etc. Most authorities accept the belief that suppurative processes due to the typhoid bacillus do not differ clinically or pathologically from those produced by pyogenic cocci, and in the author's opinion local manifestations are caused by it only when it has been deprived of its specific characteristics and can generate only the irritative poisons common to many bacterial forms.

The Diagnosis of Tuberculous Peritonitis.—H. Löhlein comments on the many difficulties in the way of diagnosticating this affection, and describes three signs that he has found of use. In over one-half of the cases operated upon by him during the last year it was found that very appreciable differences both on palpation and percussion existed in the two lateral regions of the abdomen. It is especially the change in the percussion note that is significant, and an increase in dulness on the left side, while not pathognomonic, yet gives strong presumptive evidence in favor of the existence of the disease. A logical explanation of the phenomenon may be found in the theory that the diseased mesentery naturally contracts in the line of its oblique attachment, and therefore draws the intestinal coils to the right side, leaving the other free to receive the major portion of the exudate. It has been observed and well substantiated that the site of predilection for the tuberculous deposits is found in the most dependent portions of the peritoneal cavity, and hence the lining of Douglas' cul-de-sac is nearly always invaded. By rectal palpation it is almost invariably possible to note the presence of tubercles in this region, which give to the examining finger the sensation of numerous hard nodules of varying size. The last method is a corollary from this one, and consists in making a slight opening in the posterior fornix sufficiently large to facilitate the digital examination or even to remove bits of suspected tissue for microscopical investigation, while in cases adapted to treatment by a simple cœliotomy the therapeutic indication may equally well be met by allowing this intravaginal opening to take the place of an abdominal section.

The Treatment of Scabies.—Richard Sachs, in view of the irritative or toxic properties often manifested by many of the scabiosa in use, such as balsam of Peru, styrax, sulphur, and beta-naphthol, was induced to make experiments with a new synthetic product to which the name of peruscabin has been given. This is a compound of cinnamein, styracin, and cinnamic acid, and represents the active constituents of balsam of Peru. By a long series of comparative tests, made by bringing various agents into direct contact with the parasite removed from the body, it was determined that styrax, beta-naphthol, and peruscabin possessed the greatest parasiticide power, and inasmuch as the last of these has the advantages of being odorless, of not staining the clothing, and of being free from all damaging effect on the skin or internal organs, it ought, on theoretical grounds, to be the most preferable. The drug was tried in thirty-five cases with a positive result in each, while, although in ten instances there were complicating lesions such as eczema and dermatitis, no secondary irritation was produced. The method of application is as follows: The patient takes a bath and is then anointed from head to foot with a mixture (1:3) of peruscabin and castor oil. The inunctions are repeated three times in thirty-six hours, at the end of which time the underwear and bed linen are changed. In three or four days the cure is completed by another bath, which it is well not to give too early in order that abundant time may be allowed for the remedy to reach even the deeper-seated parasites. No disagreeable symptoms whatever were caused, even though many of the patients were children, and one an infant four months old.

The Pathology and Therapy of Abscess of Douglas' Space in Perityphlitis.—By J. Rotter.

An Unusual Case of Purpura Rheumatica.—By Paul Edel.

Scottish Medical and Surgical Journal, October, 1900.

On the Surgical Treatment of Aneurisms by Excision.—Thomas Annandale urges the following advantages for this operation. If successful, the result is a complete cure. The ligatures are applied to the ends of the divided vessels, and not to them in their continuity. Even if the corresponding vein be divided and a portion of it removed, the risk of gangrene is not great. All the advantages of the antiseptic treatment can be obtained in connection with the successful healing of the wound and closure of the vessels when divided. Inflammation and suppuration of the sac or rupture of it cannot occur in connection with this method. Although as yet more experience is required, it seems likely that certain aneurisms, such as the subclavian, will in the future be treated more successfully by this method. The author believes that in the near future the treatment of all aneurisms of the limbs, provided they be tolerably circumscribed and free from complication, will be most effectively carried out by excision; and that aneurisms of a diffuse nature, owing to rupture of the sac or from other causes, will be best treated by laying open the sac and ligating the vessel at its point of communication, either by an incision through the walls of the sac or by exposing and ligating the vessels immediately outside the sac.

A Résumé of Our Knowledge of Diseases Transmissible from the Lower Animals to Man.—Theodore Shennan says that the most important of these diseases are tuberculosis, diphtheria, scarlet fever, glanders and farcy, anthrax, plague, foot-and-mouth disease, and rabies. Ten to twenty per cent. of all cows are tuberculous. Muscular tissue is rarely affected by tuberculosis, but the meat is usually infected after death, the butcher having to cut through diseased lymphatic glands. Boiling or roasting destroy the germs on the surface. Milk tuberculosis can

be prevented by boiling the milk. Merely raising it to boiling point, 100° C., and allowing it to cool is usually sufficient to render it safe, and does not injure the flavor of the milk. Diphtheria may also be conveyed in milk, and so may scarlet fever. The author takes up each disease in detail, showing how it may be transmitted to human beings by various animals.

A Case of Perforated Gastric Ulcer with Recovery after Suture.—John Shaw McLaren reports a case, and urges immediate operation in all similar ones. Infiltration anæsthesia is to be preferred to the use of chloroform or ether; the incision should be made in the middle line; the ulcer should not be excised, but simply tucked in wholesale, with first one and then a second row of sutures. If the stiffness or friability of the wall makes suturing impossible, one can drain with gauze or tube, or make artificial adhesions. When such measures are impracticable or would consume a dangerous amount of time, the stomach might be rapidly stitched to the wound and packed. The detail and extent of washing out the peritoneum with saline solution will depend on the amount of soiling and peritonitis. The solution should be very hot. Rectal feeding should be the rule for a day or two.

Jaw Jerk and Jaw Clonus.—Alexander James has found by investigation of the reaction time of the jaw jerk as compared with the knee and ankle jerks in the same individual, that the time of these muscle or tendon jerks varies directly with the distance between the muscles concerned and their nerve centres in the cord or medulla. Although differences due to individual conditions may occur, we find that the ankle clonus is slower than the knee, the knee than the hip, etc. The jaw clonus is the most rapid of all.

OUR LONDON LETTER.

(From our Special Correspondent.)

GENERAL ELECTION—WAR HOSPITALS—TREATMENT OF PRISONERS AT PRETORIA—PLAGUE AT GLASGOW—PRECAUTIONS THROUGHOUT THE COUNTRY—EXPERIMENT WITH MALARIA-INFECTED MOSQUITOS—TYPHOID.

LONDON, September 28, 1900.

WE are now in the midst of a general election, and medical questions are for the most part relegated to a back seat. The one which most frequently intrudes on conversation is the war-hospitals inquiry, but even this is less exciting than it was. The most curious point in regard to this is the tenderness with which Mr. Burdett-Coutts has up to now been treated in his own constituency, where one might have supposed political opponents would have made the most of the accumulated contradictions with which his allegations have been met. He has said that he told only the truth, but the evidence of Lords Roberts, Kitchener, and Stanley, to say nothing of numerous other witnesses, is irreconcilable with his statements. Still there seem to be some persons who accept Mr. Coutts at his own valuation, but when asked for proof of his charges they have to call up a very different class of witnesses and very singular facts. Thus I am told an audit officer in Natal spoke of a deficiency of bedsteads, but my informant should have remembered that this, if true, had nothing to do with the facts at Bloemfontein. Again, I am assured two persons had stolen patients' comforts and are in prison for the crime, but this is no proof that the Royal Army Medical Corps was to blame. Once more, I am assured that Reuter's agents are prejudiced and do not forward the evidence of all the civil surgeons; to which I reply that the agency at any rate does not suppress the evidence of Lords Roberts, Kitchener, and Stanley, and their statements satisfy most people—to which there is no answer.

Mrs. Dick Chamberlain's spite against the doctors for excluding her from the hospital at Wynberg will perhaps abate now that she finds that this was in obedience to an order of Lord Roberts himself—rather an amusing revelation even for her own set.

Another woman who was to expose a scandalous condition on the hospital ships has been before the commission, but her evidence seems likely to recoil on herself. She declared that three hundred sick and wounded men had nothing but bread and tea. On this Lord Romer said it was "impossible," they would have all died; then asked "How many did die?" Nurse Roberts replied "none." She also said the wounds were cauterized with nitric acid (!), and made other equally intelligent statements. The civil surgeon on board flatly contradicted her evidence, and told the commission she had been "dismissed as incompetent." He was corroborated by other witnesses.

Dr. A. Morison was to have produced a sensation. He had written letters to the papers alleging various things. Summoned to the commission to give evidence, he sent a letter pleading that ill-health prevented—a course which only produced the remark from the president that no medical certificate accompanied the letter.

A Mr. Edmonds, who has written letters to *The Spectator*, had to admit that he had only hearsay and no facts for his allegations, whereupon his evidence was ruled out. Some other contradictory evidence has been given—in fact, too much to epitomize. I have selected the foregoing as illustrating the kind of campaign against the hospitals that was started, and as showing that those attacked may be content to await the report of the commission.

I have already mentioned the severe condemnation passed on Dr. H. P. Veale by Lord Roberts, as the result of the inquiry into the treatment of the British prisoners of war at Pretoria. Such a verdict on a member of the profession is to be regretted. But a careful perusal of the report seems only to confirm its justice; for his own evidence seems to consist chiefly of a repudiation of his responsibility and an inability to remember the purport of letters addressed to him by the resident doctors—some of which, however, he declared he had not received.

There is no advance of the plague in Glasgow. Another case developed after my last letter. The number of patients in hospital is now twenty-two, and there are two doubtful cases. The "contacts" have been reduced to forty, showing that many have been dismissed after passing the period of isolation. The outlook is therefore encouraging, and the confidence of the sanitary authorities has been justified. But they are not relaxing their precautions, and in some respects are improving them.

The medical officers of health throughout the country seem to be wide awake and are seizing the opportunity to arouse the sanitary authorities. They are supported, too, by the local government board, which has issued an order making plague a notifiable disease, and requiring any case that may occur to be immediately reported to the sanitary authority of the place, whether urban, rural, port, or riparian. They are also to send circular letters to all legally qualified practitioners in their several districts, informing them of their duties under the regulation. The order of the board is being carried out by the various local authorities.

Stress is being laid on the mildness of the disease as seen in Glasgow, but however satisfactory this may be with regard to individual cases, it is no assistance from a preventive point of view. Rather the reverse, for in the mildest forms the idea of plague would scarcely occur unless it were known that the patient had been exposed to infection. This has been the case with some of those occurring during isolation, and it is easy to see that in such cases the danger of spreading the disease is greatest.

Above sixty persons known to have been in contact with plague patients have been treated with Yersin's serum. Two of these had very mild attacks of the disease.

You know that the experiment of residing in the most malarial locality of the Roman Campagna, carried out by Drs. Sambon, Low, and Terzi, has been so far successful. Their mosquito-proof huts have afforded them protection from the danger, and they are all well. A similar experiment under Professor Grassi has been equally successful. Now comes the complement to this method of experimenting. A son of Dr. Manson, who had never had malaria, allowed himself to be bitten by mosquitos collected by Bignami and Bastianelli, under whose care the insects had been fed on malarial patients, and forwarded to London. He has undergone an attack of tertian, the parasites appeared in his blood, and the spleen enlarged. This confirms the experiments of Grassi and Bignami which were made in Rome. As that is a malarial district, Mr. Manson has carried the proof another step.

Typhoid is on the increase in London. The cases admitted to the fever hospitals during the last five weeks have numbered respectively 33, 40, 38, 57, 89. The deaths from this disease last week fell to 14 from 23 in the previous week.

Typhoid has been for a long time, in fact all through this year, prevalent in Merthyr. The death rate has been 0.5 per thousand—about double that of the neighboring districts.

In London scarlet fever is on the increase, as seen in the number of admissions in the last four weeks successively —176, 213, 243, 269.

SUMMER VACATIONS FOR THE POOR.

To the Editor of the Medical Record.

Sir: During the last summer fourteen weekly parties of women and children were taken to "Sea Breeze," the home on Coney Island of the New York Association for Improving the Condition of the Poor. I examined these parties with a view of eliminating possible cases of contagious disease.

Among these women and children, some fifteen hundred in all, not one case of diphtheria, scarlet fever, measles, or communicable disease of like nature was found. At "Sea Breeze" one case—of pertussis—was developed during the summer. A great many children (about ten per cent.) had conjunctival inflammation; of these more than half had granular lids.

Many of the children, especially the infants, needed greatly the change from the air of the tenements to that of the sea. With pale, sallow faces, which had clammy sweat upon them, and with eyelids half closed, they were listless and without the energy characteristic of healthy children. The causes of disease especially manifested at these examinations were irregularity in feeding, and overclothing. As regards the feeding the following are specific instances: One child, who (so the mother said) was suffering from "stomach trouble," held in its fist most of a cracker. Its mouth was full of half-masticated food. It was given food "whenever it wanted something to eat," so that its digestive apparatus was almost never at rest. The baby was thin, weazened, and had a clammy sweat on its face. It looked senile. It was bottle-fed; and the bottle was given it "whenever it cried." One child during the inspection gorged himself upon a huge cruller; the mother explained, "I keep him quiet that way." Several children lunched without intermission all the while they were seen.

As regards the clothing: On one very hot day the suffering from over-much clothing was especially conspicuous. They (the babies) were almost never without heavy "belly-bands." Prickly heat was very rife among them. Almost all of them cried piteously, no doubt because they were over-clothed. They were reeking with perspiration. Six thicknesses of clothing, more than half of which were woollen, were the average. One mother had had four children die of "bronchitis" (probably pneumonia). Therefore she had the baby's thorax heavily covered with woollen garments. The baby thus clothed had its chest contracted, and normal, free action of its lungs was made impossible. The sweating caused by the superabundant clothing put it in a condition to be chilled by a chance draught. No doubt this child will go the way of the others, if it has not since then done so. Another child had a reddened face and it puffed laboriously. The mother wanted to know why it had prickly heat. Its clothing was removed. There was a heavy flannel binder, next two woollen garments, next a cotton shirt, and lastly a thick woollen cloak.

Many of the mothers were greatly in need of change and rest. There were a number of large families. One mother, thirty-seven years old, had had nine children, of whom three had died. Another of the same age had had eleven, eight of whom had died. Another, thirty-one years old, had had ten, etc. One woman had had eight children, of whom but two were living. She wept over "a beautiful baby with lovely gold hair," that died when but a few days old. The other five had died almost at the same time of diphtheria and scarlet fever, which "had been brought into the house." This woman's dissatisfaction with the part allotted to her in the universal scheme was not because of the number of children she had borne, but because they had been taken from her care. These poor women seemed much more worthy of respect than many in other social strata who—as medical men know too well—seek to forego the dignity and honors of motherhood and to avoid its perils and responsibilities.

There were a number of old women who went to "Sea Breeze." Their visits no doubt benefited them greatly. Their afflictions were those of advanced life; not a few had just come from treatment or operation in hospital.

Following are some disjointed data: A very much emaciated woman had been married at sixteen; her first child was born before she was seventeen. A child a few months old was infected with syphilis. The eruption was distributed over its body. The mother explained that the father "had been burned, and this burn turned to blood poisoning." One child had her face disfigured with impetigo contagiosa. She considered she got it "by bathing too long at Manhattan Beach." Perhaps an unclean bathing-suit was responsible. A girl of fifteen limped greatly. When somewhat over two years old she "became suddenly paralyzed in her sleep," so her mother stated. It may be this was an hysterical paralysis—in which case it is like to disappear as quickly as it came. If she should get into the clutches of a Christian Scientist, another "miracle" may be performed. A young woman had hysterical hemiplegia. This came on shortly after her marriage—to a Chinaman. A woman not forty years old, who exhibited ten children, was an optimist of the first water. I asked her, "Are you well?" "To be sure I am," said she, with a wink and a grin; "only for that I couldn't stand the racket."

41 West Forty-fifth Street.

Society Reports.

NEW YORK STATE MEDICAL ASSOCIATION.

Seventeenth Annual Meeting, Held in New York City, October 15, 16, 17, and 18, 1900.

E. D. Ferguson, M.D., of Troy, President.

First Day—Monday, October 15th.

The meeting of the Council and Fellows was a large one, and convened in the hall of the New York Academy of Medicine at 10:30 A.M. The subject for consideration was the proposed plan of reorganization. After considerable discussion over what form the by-laws should take, the whole matter was referred to a committee, which was to report back the following day.

Second Day—Tuesday, October 16th.

The first order of business was the report of the committee on by-laws. Each section was taken up in turn and discussed, and when this task had been completed the association adopted practically the fundamental plan of reorganization, though postponing for the present the adoption of certain features which had been embodied in the first draft of the by-laws. This preliminary executive work having been disposed of to the general satisfaction of the large number of members present, the regular scientific programme was taken up.

The Analogy between the Nervous Conductibility and the Electric Conductibility, and their Relation to Functional Neuroses.—Dr. A. D. Rockwell, of New York City, read this paper. He said that pathological conditions showed that the conductibility of the neuron may be complete or incomplete, according to the permeability of the nerve tract. To understand the analogy between nervous conductibility and electric conductibility one should note the behavior of the "coherer," an apparatus consisting of a tube filled with iron filings. Under ordinary conditions this tube was a non-conductor. If, however, it was placed in a solenoid, situated in the course of a current of high frequency, this tube immediately became an electrical conductor. This phenomenon had been explained on the theory that each grain of metal was surrounded by condensed ether, and that the expansion of these sheaths of ether by the electric current was responsible for the change into an electrical conductor. Neuromotor energy might be developed in the nerve cells or without them, and this overcame the natural resistance of the neurons, probably in the same manner as the particles of iron in the coherer. In the normal condition of the mind and body there was no severance of the dendrites, but in abnormal psychical conditions "the points of contact" were broken. The fundamental idea of the therapeutic value of electricity, the speaker said, was its influence upon the nerve cell and on general and local nutrition.

Cocainism.—Dr. T. D. Crothers, of Hartford, Conn., read this paper. He said that although the tonic and invigorating effect of the erythroxylon coca had long been known, the powerful intoxicating action of its alkaloid, cocaine, was a comparatively recent addition to our knowledge. The cheapening of cocaine had greatly increased its use, and its administration hypodermically being free from obvious after-effects,

the person taking it became convinced of the safety of such practice. Cocaine entered very largely into the composition of popular prescriptions. Only a small percentage of this drug was consumed legitimately in large cities. In New York, Boston, Chicago, and other cities, only from three to eight per cent. of the cocaine sold could be accounted for in legitimate ways. In the lowest sections of large cities cocaine was in greater demand than almost any other drug. When the pauper classes became addicted to the use of the drug, they became thieves in order to procure the desired supply of it. They became talkative and boisterous criminals. Large quantities of cocaine were sold in drug stores, both with and without prescriptions. Cocainism seemed to be limited to persons in early or middle life, and was most common in brain workers and neurotics. The cocaine habit was really a new disease of civilization, falling most heavily on the extremes of society. Probably the largest number of persons who became addicted to the use of cocaine had been previously accustomed to take alcohol or morphine. Cocaine became a perfect substitute for them. A small class of persons began the use of cocaine for the relief of pain or discomfort, such as that attendant upon catarrh or neuralgia. Almost every condition of pain, irritation, or exhaustion had been the starting-point of the cocaine habit.

Two Forms of Cocainism.—Cocainism appeared in two forms—the periodic and the continuous. Many of the periodic cases suffered from neurotic "nerve storms" which preceded the use of cocaine. The menstrual period in women and congestive headaches in men were common exciting causes. After a time these persons usually became continuous users of the drug. Cocaine maniacs became literally crazy until they could procure the drug.

Symptomatology.—The action of cocaine was to raise the rapidity of the heart's action, and, in large doses, to increase the respiration. In poisonous doses it caused a rise of temperature, and after a period of excitement collapse occurred. The principal action was one of exhilaration, the brain being stimulated. When given hypodermically the local sensation was paralyzed. A peculiar exaltation of brain activity was characteristic of cocainism. Later on, hallucinations and delusions developed. In the early stages, the cocainist was always self-possessed, happy, and contented, but this good feeling disappeared as the effects of the drug wore off. The stage of intoxication was marked by intense talkativeness. Many political speeches and newspaper articles, the speaker declared, brought out this peculiarity. The style of the cocainists was smooth and continuous, but their words led in no particular direction and resulted in no logical deductions. This talkativeness was in marked contrast with the broken sentences of the alcoholist. In some cases there was a mania for letter-writing, and, although sometimes slanderous, they were usually exceptionally free from bitter words or bad language. It was very common for the cocainist to believe that attempts were made on his life, and hence he was prone to carry a revolver with him. The diagnosis was often very difficult. If the patient was a physician, there would be noted slight defects in judgment or an increased indifference in ethical matters. Close observation would usually show periods at which the general mental exaltation diminished or disappeared. The cocainist was distinguished from the alcoholist by his solitary habits. A significant symptom in the later stages was the feeling of bugs crawling over the skin. No other known narcotic made such a pleasant impression upon the brain. The prognosis was always grave, cures being infrequent, and occurring only as a result of persistent and intelligent care.

Treatment.—In the treatment, the removal of the drug was indicated at once. As temporary substitutes, valerian, hyoscyamus, and other vegetable drugs of that class were recommended. The patient should be sent away to an asylum until the acute symptoms had subsided, and then he should be placed for a long time under the constant care of the family physician. The giving up of the drug was only a small part of the treatment; one must determine and remove the causes that led to the formation of the habit. One cause for the undoubted increase in the use of cocaine was the absence of legal restrictions on its sale. Another cause was its reckless use by physicians. As a narcotic or as a substitute for other narcotics, it was a very dangerous drug.

Heart Complications in Rheumatism.—Dr. James J. Walsh, of New York City, presented in this paper a résumé of some of the views expressed in the recent International Medical Congress at Paris concerning heart disease. He said that while it was generally agreed that heart complications were common in rheumatism, it was not so well settled what rheumatism really was. Recent investigations seemed to show that rheumatism was an acute infectious disease, and that, whatever might be the specific cause, it was totally unlike any of the micro-organisms at present known. It was probable that secondary infections played an important part in the production of many of the complications. It was essential, therefore, that the treatment should be directed toward securing antisepsis of the alimentary canal, as this was a common source of infection. At the congress there had been a well-grounded opinion to the effect that heart disease was more amenable to treatment than was commonly supposed. As a general rule, in painful affections of the heart it was stated that strophanthus was the drug to be selected.

Symposium on Obstetrics.—Treatment of the Patient during the Weeks Preceding the Expected Confinement.—Dr. Edward P. Davis, of Philadelphia, opened the discussion with this paper (see page 605).

Management of Normal Labor, Including the Use of Forceps.—Dr. Austin Flint, Jr., of New York City, read this paper. He urged that it be made a routine practice carefully to examine the pregnant woman at the end of the eighth month. This examination should, of course, include pelvic mensuration. The patient should be instructed to take daily walks up to the very time of labor, as this exercise would strengthen the muscles, soften the cervix, aid dilatation of the latter, and make abnormal presentations less frequent. At the time of labor the genitals should be sterilized, and an examination, first internal and then external, made in order to confirm the results of that made the previous month. It was far better to make this one examination complete and thorough than to make a number of superficial examinations at short intervals. The practice of giving a little ether with each pain was gaining ground, the administration being conducted in just the same way as with chloroform. Emphasis was laid upon the importance of observing the old rule to prevent, as long as possible, the rupture of the membranes. An anæsthetic was of great advantage in many cases, yet those who used anæsthetics most would probably see the largest number of cases requiring forceps. As soon as the head ceased to descend, and the withdrawal of the anæsthetic or stimulation failed to restore good uterine contractions, a low forceps operation should be done at once. This practice was safer than the waiting policy. Traction should be slow, gradually increasing in force until the soft parts in front of the head were stretched. Then the head should be held for about one minute before traction was slowly relaxed. After a rest of three or four minutes, traction should

be resumed. By this mode of procedure delivery could be effected with an intact pelvic floor in a surprisingly large percentage of cases. Immediately after the delivery of the head, the mouth and eyes of the child should be wiped out, if possible before the first effort at inspiration. The interval between the second and the third stage was the time when infection was most likely to occur. It was rare than an internal examination was required in normal cases after the birth of the child. Before attempting to deliver the placenta the hands should be sterilized again, and after an interval of twenty or thirty minutes the placenta should be expressed. The length of this third stage depended upon the firmness of the uterine contractions. It was his custom after the delivery of the placenta to give a hot sterile douche, as this stimulated uterine contraction, removed clots, and enabled the obstetrician to inspect the parts and readily detect even slight tears of the birth canal. The use of gloves had not proved satisfactory. The speaker said that ether possessed many advantages over chloroform, and should be used, as a rule, when the pains were of moderate severity. He had not yet employed the new method of spinal anæsthesia sufficiently to be able to express an opinion regarding its value or possible dangers.

After-Treatment of the Mother in Normal Cases.—Dr. George W. Jarman, of New York City, presented this paper. He stated that it was with no small degree of reluctance that he approached a subject about which so little could be said that had not been said over and over again. If, however, the very few remarks he might make would bring about a discussion from which something new on this subject might be heard from others present, he would be amply satisfied. The clinical history of the puerperium from the completion of the third stage of labor, he said, presented a series of physiological and pathological conditions which were necessary to the full recovery of the woman from the incidents of pregnancy and the injuries of childbirth. With the expulsion of the placenta, even though it might have come away intact, the danger of hemorrhage was not passed, and it should be the duty of the obstetrician to remain or leave some competent physician with his patient for at least one hour after the termination of the labor. Women of lax fibre were prone to have their uteri relax, and either external hemorrhage or else the formation of a clot in utero supervened. This accident could often be obviated if the adjustment of the bandage was delayed for half an hour and the fundus of the uterus frequently examined through the abdominal wall. Should this tendency of relaxation exist, grasping of the fundus and compressing it would in most instances cause it to contract and remain firm. The author was in the habit of giving one dose of ergot immediately following the expulsion of the placenta, and this medication was not repeated unless there were distinct indications. Should the relaxation not yield to the above procedure it was wise to resort to more heroic methods: the irrigation of the uterine cavity with a solution of iodine in hot water, or else the tamponing of its cavity with sterilized iodoform (ten per cent.) gauze, would bring about the desired result. Only casual mention of the hypodermic injection of ergotin, stypticin, or other remedial agents would be made, as they would naturally occur to the minds of those who were called upon to treat postpartum hemorrhage. After permanent contraction had been insured, either the nurse or the physician should apply a snug and well-fitting bandage, not with the reputed idea that it would magically restore the waist to its former delicate outlines, but because it would add distinctly to the comfort of the patient and removed the certainty of future criticism, if the patient's abdomen should perchance grow to undue proportions. The author had found it convenient after the expulsion of the placenta, and while waiting for the assurance of permanent uterine contractions, to keep the vulval region covered with a rather thick pad of cotton which had been wrung from a bichloride of mercury solution 1 : 2,000. This would absorb the rather free flow which immediately followed the emptying of the uterus. As soon as the bandage had been applied this cotton was replaced by a pad of sterilized absorbent gauze. The bed linen should then be left in a perfectly clean condition. The patient was to be allowed to turn upon her side, and would in all probability obtain a few hours of much-needed rest. Instructions should be left that the aseptic pad be frequently changed during the first twelve hours following the labor, and that the genitalia be carefully washed, at least twice per day, with a weak solution of the bichloride of mercury (1 : 5,000). It was wise to place the infant to the breast three or four times per day until the appearance of the milk, it having the doubly good effect of giving the infant nature's laxative and through the reflex nervous influence causing the uterus to remain in more firm contraction. The first visit on the part of the physician should be made within eight or ten hours after the completion of the labor. At this time he should ascertain the condition of the pulse and temperature, the amount and character of the flow, whether the patient had evacuated the bladder, the amount of sleep the patient had had, and the character and amount of nourishment taken. In highly nervous patients there was frequently a rise of temperature of one or occasionally two degrees, even in the most normal cases during the first few hours following labor. If the uterus seemed to be abnormally high in the abdomen it should be firmly compressed, and oftentimes the sudden expulsion of a blood clot would result. The amount of flow would govern the future administration of any oxytocic. The bladder should be emptied at least once in eight hours. A certain number of patients were unable to pass their urine while in the recumbent posture. Again, a few would experience a more or less marked paralysis of the bladder for a few days following labor. In either instance, if the application of cloths wrung from hot water and placed over the pubes did not bring about the desired result, the catheter must be used. The author was in the habit of using the sterilized glass catheter only, and requiring the nurse to use it under the guidance of sight, after giving her most rigid directions as regards thorough asepsis. After the third day there did not appear to be any reason why the patient should not assume the sitting posture to void the urine. If the patient had been unable to obtain the desired sleep by reason of nervousness or after-pains, some sedative should be allowed, probably the most preferable being the combination of the bromide of sodium with a small amount of chloral. Until the patient's bowels had been evacuated, that is, during the first two or three days, the diet should be restricted to one of a fluid character. It was certainly preferable that the physician should make two visits per day for the first three days, after that one per day for a week, and then at such intervals for one month as the conditions seemed to require. At the termination of forty-eight or sixty hours some gentle laxative should be administered, and perhaps no better one had ever been suggested than the time-honored castor oil. The author had never been in the habit of using the douche in the after-treatment of puerperal cases unless there was a distinct indication, such as foul lochia. It was not within the province of the paper to discuss puerperal sepsis or its treatment. The nipples should be carefully inspected for any abrasions or cracks; should such exist, a weak solution

of the nitrate of silver or glyceride of tannin might with advantage be applied. The nipples should be carefully bathed, both before and after each nursing, with a saturated solution of boracic acid, and kept as dry as possible. Usually on the third day the breasts would begin to fill up and oftentimes became hard and painful; a snug-fitting breast-binder to prevent the dragging of the breasts, and hot stupes would be sufficient to give the desired relief. It was not generally known that coffee would distinctly lessen the flow of milk. Should the patient have a superabundance of milk, a restriction of the fluids drunk and the administration of a cup of strong coffee with the morning and noonday meal would control the excessive supply. If it could be impressed on all who were called upon to conduct a woman through the puerperium that all abscesses of the breasts were caused by infection through the nipple, their frequency would be greatly diminished, and the old time-honored expressions of "caking" and "catching cold" in the breasts would lose their significance. The patient should be encouraged to lie upon her side as much as possible, as this posture would undoubtedly lessen the frequency of retroversion of the uterus. After the fourth or fifth day the author had been in the habit of having the patient assume the sitting posture for the evacuation of the bowels and bladder, as it had seemed to have a distinct advantage as regards drainage, and no untoward results had been observed. After the free evacuation of the bowels, the diet should consist of easily digestible yet at the same time nutritious food. The bowels should be thoroughly evacuated every day either by enema or some simple laxative. During the latter few weeks of pregnancy there was frequently marked torpor of the large intestine, and an unusual amount of fæces would accumulate. The comfort of the patient demanded that the rectum be thoroughly unloaded. Hemorrhoids would often cause the patient as much discomfort during the first week or two following labor as any other complication. Cold applications to the anus and the use of one-grain ichthyol suppositories would usually give relief. Should the continuance of the red flow and the height of the uterus indicate tardy involution, it was wise to hasten this process by the administration of oxytocics. The author had gotten admirable results through the use of a tablet containing ergotin, hydrastinine, and strychnine. He had never been in the habit of naming any certain time when the patient was allowed to sit up in a chair; it had always seemed to be a question of conditions rather than days, which would determine this point. However, at the end of seven or eight days the patient was allowed to sit up in bed to eat her meals and nurse the child. If the lochia had practically ceased, that is, when they amounted to no more than a scant leucorrhœal discharge, and the uterus had involuted sufficiently to be well within the small pelvis, there should be no reason why the patient should not be permitted to sit up for a short time in a chair. Should this posture cause a recurrence of the red flow, the patient should at once return to bed and remain until the flow had ceased. Before the patient had been discharged, and after all abrasions had entirely healed, a careful vaginal examination should be made; any abnormality should be corrected at once if such existed and it be deemed wise to do so. Should, however, a later operation be necessary for this purpose, the attendant should be certain to acquaint some mèmber of the family of this fact, as it would undoubtedly save future criticism on the part of either the patient or the gynæcologist. In conclusion he would accentuate these points: the after-treatment should be made as simple as was consistent with thoroughness; the attendant should see to it that all who came in contact with the patient followed the laws of surgical cleanliness not only in letter but in fact; he should bear in mind that it was the duty of the obstetrician to see to it not only that his patient recovered from the dangers of childbirth, but that she should be left in a normal condition, with healthy pelvic organs.

After-Treatment of the Child in Normal Cases.—Dr. Bernard Cohen, of Buffalo, presented this part of the subject. He said that as soon as born the child should be turned on its right side to favor the establishment of the proper circulation, and as soon as possible the eyes, nose, and mouth should be wiped, and washed with a solution of boric acid. Ligation of the cord should be delayed for several minutes, not so much with the idea of adding two or three ounces of blood to that circulating in the infant's body, but because this course seemed to lead to a better circulation. The cord should be stripped of its jelly for some distance from the umbilicus, and then ligated so as to give a short stump. A narrow tape, or half a dozen strands of cotton thread, formed the best materials for the ligature, which should, of course, be sterilized. As he had never met with a case of cord infection he saw no reason for cauterization of the stump, as some had recommended. Should there be any suspicion of gonorrhœa or local infection in the mother, the baby's eyes should be treated by the Credé method. After an inspection of the child to determine the possible presence of abnormalities of development, its body should be well anointed with oil, and the process of cleansing be proceeded with. The cord should be dressed with powdered boric acid. A tight belly-band seemed to him to be conducive to umbilical hernia. For the first few days of life the physician should keep himself informed regarding the proper secretion of meconium and urine.

Ophthalmia Neonatorum; its Pathology, Prophylaxis, and Treatment.—Dr. John E. Weeks, of New York City, discussed this subject. He said that ophthalmia neonatorum usually developed about the third day, being announced by light redness, swelling of the lids, and the presence of a discharge. When the discharge first appeared after the fourth day one could be almost sure that the ophthalmia was the result of gonorrhœal infection, and this, too, whether it was of a mild or severe type. He had made numerous observations on this point extending over many years, and they all justified this conclusion. Many gonorrhœal cases were so mild that they could be distinguished only by an examination for gonococci. Out of about fifty thousand blind persons in the United States, five thousand lost their sight through ophthalmia neonatorum. The prophylactic treatment consisted in the instillation of various solutions according to the Credé method. The sublimate solution and the two-per-cent. solution of nitrate of silver gave the best results. Eighteen times as many children suffered from ophthalmia neonatorum in institutions in which this prophylaxis was not employed as in those where it was regularly carried out. It was, therefore, advisable to employ prophylaxis in all cases, the drops being introduced into the eyes of the infant just after it had received its first bath.

Treatment.—By cold applications to the lids, the temperature of the conjunctival sac could be reduced to 88° or 94° F., according to the thickness of the lids. At this temperature the gonococci grew much less rapidly than at the normal temperature of the part. The conjunctival sac should be cleansed frequently by the use of a non-irritating aseptic or mildly antiseptic solution. Many preferred a three-per-cent. solution of boric acid, though a solution of sublimate, 1 : 15,000 or 20,000, might be used. The fluid should be tepid, and should be used freely and sufficiently often to keep the parts free from secretion—usually once in twenty or thirty minutes. Care should be observed

not to press on the eyeball or cause an abrasion. This treatment should be kept up until the lids assumed a normal condition. Cold applications should also be used continuously for from one to four hours at a time, and should be repeated three times daily. Cotton pads were preferable for this purpose; they should be changed every minute or two. The cold applications should be discontinued when the swelling of the lids subsided. A one-per-cent. solution of nitrate of silver should be applied to the entire surface of the conjunctiva once daily after all secretion had been removed. It should be made daily until the secretion ceased. If the cornea became involved, atropine should be used.

The Major Obstetrical Operations from the Standpoint of a General Practitioner.—Dr. Edward Reynolds, of Boston, in considering this topic, divided the cases into two classes, viz.: (1) Those in which operation was elective and was done early, and (2) those unfavorable cases in which the operation was not undertaken until after infection or exhaustion from a tedious labor. He had been surprised to find, as a result of a careful search of the literature, that those operations were attended by a large fœtal mortality—about fifty per cent.

Cæsarean Section.—It had been assumed that the mortality from this operation was only between twenty-five and forty per cent. If considered as a whole, without reference to the classes of cases, this statement was correct, but it was nevertheless misleading. In an analysis that he had made of one hundred and fifty cases, eighty-nine favorable cases had had no mortality, whereas sixty-one unfavorable cases gave a mortality of thirty-three and one-third per cent. When extirpation of the uterus was added to Cæsarean section, it was probable that the maternal mortality was slightly greater in the favorable cases, and in the unfavorable cases a little less than that of the classical section. There was practically no fœtal mortality from Cæsarean section if the child was in good condition at the time the operation was undertaken.

Symphyseotomy.—In connection with the operation of symphyseotomy about the only maternal mortality was that due to the performance of this operation in cases in which the degree of disproportion was too great to admit of easy extraction afterward. In these cases there was also a considerable maternal mortality. It was worthy of note that the mortality from symphyseotomy in the unfavorable class was only very slightly larger for both mother and child than in the favorable cases.

Selection of Operation.—When the mechanical relations would render forceps or version unusually difficult or prolonged, and the mother's condition was favorable, Cæsarean section was the operation of choice. When the mechanical conditions made the intrapelvic delivery of an intact child at term impossible or very difficult, the great superiority of Cæsarean section over induction of premature labor was apparent. In the unfavorable class, however, symphyseotomy was the operation of choice, provided always the degree of mechanical difficulty permitted of its application. When in the unfavorable cases symphyseotomy was impracticable because of the disproportion between the maternal and fœtal parts, craniotomy should be unhesitatingly chosen.

Prophylaxis.—The keynote to prophylaxis was pelvimetry. It was most easily carried out by determining from palpation the ease with which the fœtal head could be made to descend into the pelvis. If in a primipara with rigid uterus and abdominal wall, the head was well wedged in the brim at the beginning of labor, the case was probably within the safe use of the forceps. If, on the other hand, in such a patient the head was above and had not entered the brim, or was not pressed against it firmly, there was strong possibility of the presence of a disproportion between the fœtal and maternal parts. When the woman had lost one baby from mechanical obstruction in a previous labor, he thought it should be the general rule to offer her the advantages of a cutting operation.

Puerperal Sepsis: its Pathology and Treatment.—Dr. William R. Pryor, of New York City, read this paper (to appear in a future issue).

Symposium on the Blood.—Technique of Blood Examination.—Dr. Edward K. Dunham, of New York City, opened the discussion with remarks on this subject. He said that the blood for examination was usually obtained from the lobe of the ear by puncture with one nib of a new steel pen. The first drop of blood exuded was usually discarded.

Specific Gravity.—The specific gravity of the blood might be determined in two ways: (1) By the use of a delicate balance, and (2) by suspending a drop of blood in a mixture of chloroform and benzol. If the specific gravity of the mixture coincided with that of the blood, the latter would neither rise nor sink in the mixture. If the drop of blood rose, it showed that the mixture was heavier than the blood. It was made lighter by adding benzol, and heavier by the addition of chloroform.

Reaction.—The reaction of the blood was not easily determined, requiring the use of delicate standardized solutions and sensitive litmus paper, and was not likely to be determined by the clinician.

Rapidity of Coagulation.—A very simple method of determining the rapidity of coagulation consisted in filling a graduated capillary tube with blood, and alternately introducing and withdrawing a horsehair. This horsehair did not become stained with the blood until coagulation began. When this process was complete, the clot would no longer stain the hair.

Hæmoglobin.—The majority of methods for determining the hæmoglobin required the measuring off in a graduated pipette of a quantity of blood freshly drawn from the patient. This blood was usually diluted with distilled water, and then the tint of this solution was compared with some standard color. By the admixture of distilled water the hæmoglobin was extracted from the blood corpuscles, and its color was imparted to the water. There were several important sources of error in connection with the use of these instruments. One of these was the lack of uniformity in the distribution of the hæmoglobin through the water; another was the personal equation. The latter, the speaker thought, amounted to about five per cent. An instrument known as the ferrometer was designed to determine, not the amount of hæmoglobin directly, but the amount of iron in the blood, as the latter roughly corresponded with the amount of hæmoglobin. A measured quantity of blood was evaporated to dryness, incinerated, and dissolved in an aqueous solution of bisulphate of potassium. Sulphocyanide of potassium and dilute hydrochloric acid were then added, thus forming the blood-red cyanide of iron. This color was then compared with a standard solution of this salt of iron, and the amount of iron, and indirectly of hæmoglobin, was then calculated.

Blood Count.—The number of red or white blood corpuscles present was determined with the aid of the hæmocytometer. The hæmatokrit did not give very accurate results.

Leucocytes in Relation to Surgical Diagnosis.—Dr. Joseph C. Bloodgood, of the Johns Hopkins University, discussed this topic, confining his remarks to the diagnostic aid afforded by blood counts in abdominal surgery, particularly in cases of appendicitis, peritonitis, and obstruction. The speaker said that all leucocyte counts above 7,000 might be looked upon as a leucocytosis.

Appendicitis.—In chronic cases of appendicitis admitted to the hospital after an attack he had found, with few exceptions, that the leucocyte count was below normal. In cases of acute appendicitis admitted at the end of the attack, the leucocyte count had been between 10,000 and 15,000. In cases of acute appendicitis admitted in the first few days, and not operated on, the leucocyte count had varied between 8,000 and 22,000. In these cases as the symptoms abated the leucocyte count rapidly fell. In cases of acute diffuse appendicitis in which operation was done, the blood counts had varied between 7,000 and 25,000, and in gangrenous appendicitis between 13,000 and 25,000. In cases in which the appendix had been distended with pus, the count had varied between 15,000 and 35,000. In the acute cases of appendicitis, if operation had been delayed, there would be, along with the increase in the symptoms, an increase in the leucocyte count. If the local symptoms in a case of appendicitis had subsided, the leucocytes usually disappeared. A rising leucocyte count, with symptoms of appendicitis, was, as a general rule, an indication of danger. If, in a case giving a history of appendicitis, but without distinct physical signs of this disease, the leucocyte count was large, one might feel reasonably sure that there existed an abscess so deeply situated that it was not palpable. In cases of appendicitis with abscess, and presenting acute symptoms, the leucocyte count had varied from 6,000 to 60,000. The absence of a leucocytosis did not exclude a small abscess, but the presence of a leucocytosis was almost pathognomonic of the presence of an abscess. In an acute attack, a rising leucocytosis was almost invariably an indication that the patient was getting worse—in other words, there was abscess formation, gangrene, or beginning peritonitis. With a leucocyte count over 20,000, in a case of appendicitis, he would lose no time in operating.

Peritonitis.—Some of the highest leucocyte counts occurred with peritonitis. Most of the blood counts in these cases had varied from 7,000 to 40,000. As a rule, at the outset, with the exception of typhoid fever, the leucocyte count was very high. It increased for a few hours and then fell to 7,000, and to below the normal before death. In cases of peritonitis of not more than twenty-four hours' duration the counts had varied from 14,000 to 22,000, and all these cases had terminated fatally. A high leucocyte count was not of much significance in the first twenty-four hours of a peritonitis. If this persisted after thirty-six or forty-eight hours, the prognosis was proportionately good. In cases of peritonitis from typhoid perforation, the blood counts had varied from 7,000 to 23,000. He had found, almost without exception, that any pathological condition producing obstruction was followed in a few hours by a rise in the leucocyte count.

Obstruction.—In the first forty-eight hours, obstruction, without gangrene or peritonitis, gave a leucocyte count of only 6,000 to 16,000, while in cases of obstruction with gangrene the leucocyte count was higher. The higher the count and the shorter the duration in these cases the greater the probability of gangrene. If there was a count above 20,000 in the first twenty-four hours, the chances were that gangrene was present. After the third day, if the leucocytosis remained high, the prognosis was good, excluding gangrene and peritonitis. During the past summer, Dr. Thayer had made a most laborious and exhaustive examination of the records of typhoid cases for a number of years, and had, as a result, come to the conclusion that there was rarely a rise in the leucocyte count in typhoid fever without some associated complication or aggravation of the disease.

Pernicious Anæmia.—Dr. Alfred Stengel, of Philadelphia, read this paper. It was certain, he said, that this disease resulted from the rapid destruction of red blood corpuscles, and that the source of these hæmolytic agents was the gastro-intestinal tract. It followed, therefore, that pernicious anæmia was not a primary disease. But it should be noted that the disease did not invariably follow upon the grave gastro-intestinal disorder alluded to. In certain cases a special infection might be added, or there might be a disturbance in the process of hæmatogenesis. The number of red blood corpuscles was reduced below that seen in any other condition; these corpuscles presented marked changes in size, shape, and staining-relations; the total number of leucocytes was usually reduced, and the uninuclear elements, especially the smaller forms, were nearly always more numerous than the polymorphous cells. Megalocytes and an average excess of the red blood corpuscles were more common in this than in any other disease. Irregular staining was more striking than in any other disease. The large nucleated corpuscles were more regularly present in this than in other forms of anæmia. Dr. Stengel said he would regard as pernicious anæmia a case presenting the usual clinical symptoms of this disease, together with a blood count of the red blood corpuscles of 1,500,000 and a proportionate number of leucocytes. He had never met with a patient who had been cured, but he had had them under observation for four or five years. None of them warrants a hopeless opinion regarding its treatment.

Leukæmia.—Dr. C. Y. White, of Philadelphia, took up this topic, dealing with it chiefly from the laboratory side. He recognized two varieties, (1) spleno-myelogenous leukæmia, and (2) lymphatic leukæmia. The first form was characterized by a progressive pernicious anæmia accompanied by all the forms of red-cell degeneration, and by polymorphic leucocytosis. Lymphatic leukæmia, on the other hand, was associated with less marked anæmia, less evidence of red-cell degeneration, and a less pronounced leucocytosis, which was chiefly formed by the lymphocytes. Cases of leukæmia had been reported in which the red cells had been less numerous than the white. With the decrease of the red cells there was a diminution in the hæmoglobin. In addition there were two pathological cells present in large numbers, viz., the myelocyte and the eosinophilic myelocyte.

Parasites in the Blood.—Dr. Leon S. Le Wald, of New York City, spoke on this subject, dwelling particularly on the very recent interesting experiments in regard to the relation of mosquitos to malaria. He said that Drs. Manson and Ross, of England, had proved within the last month most conclusively that malaria was transmitted to the human subject by mosquitos. Mosquitos raised in the laboratory, and known to be free from malarial infection, were allowed to suck the blood of a person in Italy suffering from malaria, the type of which had been determined by microscopical examination of the blood and identification of its contained parasites. These mosquitos were then sent to London and allowed to bite Dr. Manson's son, a young man who was perfectly healthy at the time, and free from malarial infection. He promptly developed, on September 13, 1900, the characteristic signs of true malaria, and examination of his blood on September 16th showed many tertian parasites—the same form present in the blood of the Italian. After a few days, quinine was administered freely, and in two days more these parasites had disappeared. A week later the young man was well again. Another interesting experiment conducted this summer was that of Drs. Sambon and Low, who took a hut with them to the most intensely malarial section of the Roman Campagna. Here they lived for several weeks without developing malaria, although newcomers to that region almost invariably became promptly infected.

All that they did was to remain in the house between sunset and sunrise, and took unusual precautions to prevent being bitten by mosquitos at any time while there. The connecting link between these two most important experiments was to be found in the discovery within the bodies of these mosquitos, known to transmit malaria, the flagella, thus demonstrating beyond all doubt that the mosquito is the intermediary host of the malarial parasite. It should be noted that this statement applied only to certain species of mosquitos, and this explained the fact that malaria was unknown in many places where ordinary mosquitos were abundant.

The Value of Blood Examinations in the Diagnosis of Trichinosis, with a Report of Two Cases.—Dr. H. C. Gordineer, of Troy, read this paper. He said that mild cases of sporadic trichinosis were doubtless overlooked by all. Such a confession had been made by no less an authority than Osler. The fact that there was an enormous increase of the eosinophiles of the blood in cases of trichinosis had directed new attention to the study of the blood in this disease. Dr. Brown, of the Johns Hopkins University, had presented a classical study on this subject. This author advised that systematic blood examinations be made in doubtful cases. The observations of Brown had been abundantly verified by Cabot, Gwynn, Atkinson, Stumpf, Blumer, and Newman. The percentage of eosinophiles was far in excess of that observed in any other disease. The first case reported in the paper had been seen in the Samaritan Hospital, in the person of a man who had been eating freely of "blood sausage." There was a peculiar swelling of the face, particularly about the eyelids, and there were also swellings over the tibia, together with a soreness of the muscles and marked anæmia. Examination of the blood showed seventy-seven per cent. of eosinophiles, and examination of the muscles demonstrated the presence of the trichinæ. The second case was that of the father of the first patient, who had been in excellent health up to three months previous to coming under examination. He had then been taken ill with fever, diarrhœa, and cramps all over the body. He, too, had eaten freely of the sausage. The man had walked unassisted to the hospital. He was pale, but much less so than the son, and there was only slight swelling of the eyelids. His temperature was 99.5° F. Examination of his blood showed 29.9 per cent. of eosinophiles. Microscopical examination of the biceps muscle showed no trichinæ, but the characteristic areas of degeneration were visible. The speaker said that he had also seen a case bearing on the negative value of blood examination. A man had been accustomed to eat freely of raw ham, and about this time had developed all of the more characteristic symptoms of trichinosis. The muscular soreness was such that slight motion caused extreme pain. A great many microscopical examinations of the ham were made, but without showing any trichinæ. This man's blood showed an enormous number of leucocytes, but the percentage of eosinsophiles was very small. The patient would not consent to the removal of a portion of muscle for microscopical examination. So severe was the disease that it was expected the man would die, but he eventually recovered. The case was probably one of polymyositis.

Officers Elected.—*President*, Dr. John A. Wyeth, of New York; *Vice-President*, Dr. A. A. Hubbell, of Buffalo; *Secretary*, Dr. Fredrick Holme Wiggin, of New York; *Treasurer*, Dr. E. H. Squibb, of Brooklyn; *District Presidents*, Charles B. Tefft, of Utica; First District, John T. Wheeler, of Chatham; Second District, Theron A. Wales; Third District, W. H. Thornton, of Buffalo; Fourth District, Dr. J. C. Bierwirth, of Brooklyn.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, October 8, 1900.

William McCollom, M.D., in the Chair.

A Case of Hypospadias.—Dr. Carl Beck presented this patient. The child was only five months of age when operated upon. The hypospadias was of the balanic type and of small extent. There was no reaction and the result was perfect. This was the youngest child he had ever operated upon for this condition.

Forward Dislocation of the Urethra after Extensive Ulceration of the Penis.—Dr. Beck also presented this patient. A colored man, twenty-four years of age, arrived from his home, Nassau (Bahama Islands), in a desolate condition. There had been a destruction of the urethra by a phagedenic chancre. The glans was disfigured by ulceration in such a manner that two glandular halves had formed. The anterior third of the pendulous portion of the urethra was also totally destroyed. There were retention of urine, cystitis, and extensive œdema of the penis as well as of the scrotum which required many weeks of energetic treatment before a plastic operation could be performed. In spite of all precautions the first attempt at dislocating the urethra (see abstract of paper which follows) proved a failure, probably due to the immense tension caused by the efforts in protecting the large deficiency left by the ulceration. Lateral flaps had been taken freely from the integument of the penis for the purpose. The greater portion of the deficiency being covered by this attempt, the second effort was made easy, the urethra remaining attached at its new orifice. Finally, the integumental gap remaining below the glans was covered by a quadrilateral flap taken from the scrotum. So the final result could be called a very good one, the patient passing his urine in a normal stream and not showing any abnormalities during erection.

Hydrotherapy for Typhoid Fever in Private Practice.—Dr. S. Baruch read a paper with this title. The Brand bath, he stated, consisted in the use of water at 70° F. with friction, used for fifteen minutes, every three hours when the rectal temperature was at or above 103°. Hospital statistics he did not consider at all reliable. In statistics referred to, soldiers about the same age, the same weight, taking the same food, exercise, rest, sleep, etc., with typhoid fever gave reliable data showing a reduction of mortality from twenty per cent. to 2.7 per cent. when the strict Brand method of treatment was applied; these results were obtained by a reduction in the complications. The most convincing proof of the efficacy of this treatment was shown in the fact that it was now taught in our schools and hospitals. Yet it was not enough employed in private practice. Dr. Baruch first made a plea for the application of this method in 1889, since which time the schools and hospitals had taken it up and taught the method. In applying the Brand method the temperature of the bath was at first 85° and in each bath the temperature was lowered 5° until 65° was reached. He emphasized the importance of applying friction. Patients should be carefully dried without rubbing. In private practice an ordinary tin tub, six feet long, obtainable at almost any store, may be used. This tub could be placed alongside the cot. A piece of gas hose was attached to the cold-water faucet. The tub could be filled with water at the required temperature in this way. When the tub was one-half full the patient was, with great care, placed in a hammock and gently swung into the tub. After the bath the patient was gently raised by means of the hammock, laid on the sofa, dried, and allowed to rest. In most cases the patients then fell into a slumber.

The patient should be dried without friction. The bath should be repeated in four hours so long as the temperature was at or above 103°. The water in the tub did not require renewing, unless soiled, for forty-eight hours. Before the patient was placed in the bath four ounces of coffee, or whiskey, might be given if necessary. Alcoholic stimulants were rarely required. Six ounces of milk and four ounces of ice-water should be given alternately every two hours. Patients who were secreting much below the normal quantity of urine he had seen secrete, after this treatment, from eighty to one hundred and thirty ounces in twenty-four hours.

Substitutes for the Brand Method.—When the reaction was imperfect, or the relatives objected to the treatment, some other procedure than the Brand became necessary. In selecting some substitute one should bear in mind that the nearer we approached the Brand method the better results would be obtained. Cold sponging, as usually applied, was really a damp mopping of the skin. Ablution he considered a valuable substitute. The water should have a temperature of 80°, and be applied first to the back with friction, and then to the front. It might be repeated every three hours when the temperature was at or above 103°. Affusion might be combined with ablutions. An oil-cloth, properly covered by a cotton sheet, was placed beneath the patient. The head of the bed was raised. A large pan was placed below to receive the water. An attendant stood at the head of the bed and formed a trough. The patient was then turned in order to make the back accessible. The water that was poured over the black should have a temperature of 85°. The parts should be rubbed with the flat hand. When the parts ceased to be warm then some other part should be treated. In the late war these baths were called the "slush" baths. Towel-baths were really a modification of the sheet-baths. The patient was laid on a wet sheet and water at a temperature of 60° was poured from a cup. Each treatment might reduce the temperature 2°. Friction was applied after each pouring of the water. In the use of towels, they were spread over the part and water at 60° was poured from a cup over successive parts, friction being applied. The entire body, except the lower one-third, should be so treated. The ice-rub was Dr. Hare's substitution. After proper protection of the patient ice was rubbed over the patient's body, active friction being used with the unemployed hand. If ice be rubbed rapidly there was no murmur on the part of the patient; rubbing rapidly was the key to the whole thing. The doctor had never seen a patient in a condition of blueness or cyanosis when properly rubbed. Cold should be applied to the head while applications were being made to the body. This rubbing and application of cold should be thoroughly made to the muscles of the body and thighs, for it was in these situations that there seemed to be a great reservoir for heat. The application of cold and friction to the posterior surface of the body seemed to be more important than to the anterior. Stress was laid upon proper technique. Some nurses thought it was only necessary to soak their patients. It was a good rule to follow to use such a temperature of the water as would produce the desired effect, whether applied by rubbing, by the tub, by the tepid or by the hot baths. One should bear in mind that the lethal element in typhoid fever was a toxæmia which overwhelmed the nervous system, according to its intensity; to this toxæmia might be ascribed the high temperature, stupor, delirium, etc. The application of cold here produced a shock, which was followed, when judiciously applied, by a reaction, the stimulating effect of which was conveyed to the central nervous system.

Dr. R. E. Van Gieson, of Brooklyn, said the good effect of the Brand treatment was not so much in the lowering of the temperature as it was in keeping up the action of the heart until the toxins had been eliminated. It was difficult to get patients, or their relatives, to submit to the original Brand method, and he hoped that some gentler method might be found which would overcome this prejudice. In using the ice-rub he had had made an ice-clip which enabled one to retain hold of the ice.

Dr. William McCollom, of Brooklyn, stated that pyrexia might be considered normal in febrile disease. It had been suggested that it was a conservative process of protoplasm and nerve energy in destroying toxins of the invading microbe. If this was true the normal temperature of febrile disease should not be lowered to a marked degree by antipyretics. The use of hydrotherapy in continued fevers was very old; it was much in favor at the commencement of this century. Galen clearly defined this method in early times. In the early years of this century Dr. Currie, of Liverpool, did much successful work in advocating and introducing it, or reviving an old practice. Dr. Currie seemed to have carried out the modern principles of hydrotherapy ably and systematically. Dr. Jackson, also, did much in the same line at the same time. In fact the management of typhoid fever, then called typhus mitior, nearly a hundred years ago, was much the same as the best methods of to-day. Heat reduction by heat abstraction was transitory and of little use in typhoid fever. He had long been of the opinion that the mere extraction of heat by cold applied to the surface was not directly therapeutic, but that it acted as a neural stimulant, increasing and toning the action of the nerve centres of respiration, circulation, metabolism, elimination, etc. Winternitz, at the International Congress at Rome, demonstrated that cold applied to large surfaces of the body, when good reaction followed, led to remarkable results: it increased the leucocytes, the percentage of the hæmoglobin, and the specific gravity of blood. Metabolism, constructive and destructive, was promoted, and if, according to Vaughn, the leucocytes were a form of destructive metabolism which destroyed the microbes and toxins of fevers we had a plausible theory of the reduction of pyrexia by the increase of the leucocytes in the blood by the frequent cold bath. It had been demonstrated by Jurgensen, Roque, and Well, that the cold bath increased the specific gravity and the percentage of urea in the urine to a great extent. Leibminster and Voit had shown that the cold bath increased the elimination of carbon dioxide by the lungs. When fever resulted from toxæmia heat reduction must be effected by the elimination of the toxins. Heat reduction did not destroy microbes, and artificial antipyretics were worse than useless if they did not stimulate the nerves of organic life, and increased elimination and metabolism. To invigorate and increase the physiological activities so as to effect the elimination of poisonous products should be aimed at. Cutaneous transpiration caused by the coal-tar products helped elimination in one direction, but they were objectionable because of their depressing effects.

The Operation for Hypospadias.—Dr. Carl Beck read this paper. Hypospadias, he stated, was one of the most frequent malformations affecting the human body. Rennes detected one in eight hundred recruits of the French army. The number of cases had been underestimated, and this was explained by the natural aversion of the unfortunate patients to mention their deformity. The common balanic form was considered. Fecundation was almost impossible on account of the wrong direction of the urethra. Among more than one hundred married hypospadiacs he had examined he found that none had children.

Early Operations and Reasons for their Failures.—Early operations were based on the principle of direct union of the margins of the abnormal groove. Disappointments were great, and this fact caused small wonder when we considered the small space of the operative field, the necessity of introducing a catheter, the constant contact with urine, and the pre-antiseptic *modus operandi*. Failures were readily understood when we considered the difficulties encountered in the after-treatment. First, a foreign body, a tube, must be introduced into the newly formed wound channel, kept *in situ* with great difficulty. Again, the direct contact of such decomposing elements as those of the urine, as well as the mechanical injury caused by the stream itself, interfered with the aseptic course of the operation.

Extensibility of the Organ.—The theoretical reflection that the extensibility of an organ which was able to change its volume to such a marked degree during erection could be utilized for surgical purposes, gave him the first impetus to his experiments. This mobility extended over the whole movable portion of the penis; it was absent in the perineal and pelvic sphere. In adults, the length of the *pars mobilis* amounted to 8–9 cm. in the relaxed, and to 15–16 cm. in the erected condition. In children of five years 5.5 cm. could be assumed to be the average. The calibre of the urethra in adults could be estimated at 6 mm. in moderate distention, and at 10.5 mm. in forced dilatation. The enormous abundance of elastic fibres which characterized the mucous membrane of the urethra along its cavernous portion could be regarded as an expression of its enormous extensibility. If the difference in length between the erected and the relaxed penis could be regarded as fairly proportional to the degree of the extensibility of the urethra, it could be understood at once what a surprisingly long area could be covered with the mobilized urethra. Instead of forming a new urethra he utilized the existing one, dissecting it free and dislocating it forward so that a new canal need not be created, the existing urethra doing the service of it.

Technique of the Operation.—The most minute aseptic precautions were taken. An incision was made from the centre of the abnormal urethral opening, through the skin, to the posterior third of the pendulous portion. At the upper end of this incision a second one running nearly transverse through the integument was added, while the glans was stretched upward. This incision encircled the lower third of the neck of the penis immediately below the coronary sulcus. The skin flaps were dissected back to expose the lower third of the penis. While the wound margins were firmly retracted downward, the urethra, together with its corpus cavernosum, was dissected from its bed. After having exposed the urethra freely so that it could be easily drawn to the top of the glans, the latter was tunnelled by creating two flaps which were formed by making a lateral incision along each side of the groove. These flaps must be raised so far that the dislocated urethra could be placed into the wound bed. The orifice was fastened at the top of the glans with four iodoform-silk sutures of moderate strength. The flaps formed from the glans were next united above. The cosmetic effect might be improved by uniting the small cross section of the skin above in a longitudinal direction. This mode of attaching the urethral opening to the new meatus, which required considerable thoroughness, he recommended as the general way of procedure. The tunnelling of the glans could be done in a simpler manner by perforating it with a narrow bistoury. The cosmetic result of this shorter but more brutal procedure was not so perfect. It was only in cases in which but a shallow groove, or none at all, was present, or whenever through preceding operative efforts the lower glandular portion was infiltrated by much cicatricial tissue, that he had selected this mode of tunnelling the glans *in toto* by thrusting a narrow straight bistoury through it from below upward and well behind the sulcus which would normally be the fossa. Thus, a new meatus was created about a quarter of an inch behind the topmost angle of the sulcus. The point of emergence of the bistoury was enlarged by turning it to the right or left, making an incision at each side. After the knife was withdrawn, a long narrow forceps was passed from above through the channel and the urethra grasped. Now the free end of the urethra was drawn through the channel perforating the glans, and its opening attached by means of four iodoform-silk sutures to the new meatus. This was done in the same way as already described. The flaps below the glans were also united in the same manner. When choosing this mode of attachment it was advisable to support the urethra by two catgut sutures, uniting its wall inwardly to the sulcus of the new canal. The after-treatment was very simple. The penis was surrounded by an iodoform-gauze dressing so far that a free space for the new orifice was left. This region was then covered with compresses saturated with Burow's solution, which were changed frequently.

Dr. John H. Branth said that hypospadias in its broadest sense was generally mistaken for hermaphrodism (double sex), but he doubted that true hermaphrodism existed in man. There might be a condition in which one or more parts of an organism were wanting or deformed, but that a condition of double sex ever existed he disputed. Like cleft palate, hypospadias was a cleft in the floor of the urethra extending backward toward, and sometimes including, the perineum to a variable extent up to the membranous urethra. The fetus in the first two months was normally hypospadiac. Incontinence did not exist as the sphincter of the bladder was not involved. The testicles were generally in the abdomen in this deformity. A fancied resemblance to the female vulva was made apparent when the cleft separated the scrotal pouches which may look like the labia majora. In this cleft, somewhere between or anterior to the scrotal pouches, was the stump of the urethra issuing from the bladder. Anterior to this opening or fissure was either a wholly or partially patulous urethra, or it might be a solid cord-like structure. The penis was short and thick and, on sexual irritation, would be arched upward, the corpus cavernosum and corpus spongiosum expanding less than the dorsum of the penis. The urine was very often delivered backward. The disturbances were functional. If the urethral opening was not far from the glans, no disturbance existed and such a patient would soon learn to hold his penis upward to prevent wetting his clothes. Sexual indulgence and impregnation were possible in the milder cases of hypospadias. The severer cases, complicated with contraction of the lower section of the penis, had been treated by Dr. Physick by resection, cutting out a wedge-shaped piece (base upward) from the corpus cavernosum. Another plan was to make cross sections like a tenotomy in the lower portion and then hold the penis straight by splints until healed. After this the building of a urethra could be attempted. The skin in all the cases he had seen was so redundant and so distensible in this region, that one was not at a loss to find material to build a canal for the missing urethra. He had succeeded satisfactorily by cutting the external half of the prepuce as a flap, and inverting it backward over the defective urethra. This flap had its raw side out. Then he cut along the two sides of the urethra and dissected up the skin. The edge of the everted, turned-back flap was then sewed over the sides of the urethra and the lateral flaps over this were

brought together by stitches. This brought the two raw surfaces together all along the urethra to the prepuce. The skin of the prepuce formed now the inner wall of the canal. The prepuce had no hair, and incrustations would not occur. The canal was formed over a rubber drainage tube in the slit prepuce, which remained in position for a few days if possible, until the stitches were ready to come out. Sometimes it might be well to permit a urinary fistula until the anterior canal was healed, and later to close this fistula, when the urinary canal would be continuous to the bladder. A forceful ejection of semen could hardly be expected from such a urethra, and impregnation was more or less accidental. In juxtaposition to hypospadias he referred to epispadias, a fissure in the roof of the organ. A little more than a year ago he had presented to the society two cases of exstrophy of the bladder, in which epispadias existed. He brought forward a theory that this deformity occurred from a horizontal twist in the fœtal os pubis, bringing out above the os pubis the penis, which condition is always found in exstrophy. Investigators all remarked that it was unexplainable why in epispadias the urethral structure was above the corpus cavernosum. His theory of twisting the parts seemed to furnish an explanation. Complete hypospadias he considered of rare occurrence, while cleft glans was quite frequent. Hypospadias was sometimes hereditary. Baran was quoted as stating that epispadias occurred once in four hundred and fifty cases of hypospadias. Rennes found ten cases of hypospadias in three thousand conscripts. Marchal did not find a single case of epispadias in sixty thousand conscripts.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 13, 1900:

	Cases.	Deaths.
Tuberculosis	276	140
Typhoid fever	139	27
Scarlet fever	61	4
Measles	41	2
Diphtheria	181	26
Laryngeal diphtheria (croup)	8	4
Cerebro-spinal meningitis	0	3
Varicella	7	0

An Alleged Doctor's Industry.—A warrant was not long since issued for the arrest of a man, calling himself a physician, whose only occupation seems to have been the theft of typewriting machines. His way was to hire typewriters, paying the first instalment of $3 in advance, and thereafter persuading the collectors not to enforce payments for several months. When these became too importunate the man would disappear. He is known to have obtained twelve machines in this way, paying for each the $3 rental, and selling them for from $20 to $50, according to make and age.

Large Vesical Calculi.—We have been able, says the *Indian Medical Gazette*, to collect a few records of gigantic stones which have formed in the bladder. The largest which we have got accurate details about is one removed by Lieut.-Col. G. J. Bamber, I.M.S., when civil surgeon of Guzrat in 1893. It weighed on removal twenty-five ounces, and is now twenty-three ounces, and is still in the possession of Lieutenant-Colonel Bamber. It filled the bladder almost exactly and had to be removed by a suprapubic operation.

The Baccelli Treatment of Tetanus.—Forty cases of tetanus are now reported as having been treated with carbolic acid; four patients died and thirty-six recovered.

The American Red Cross in India.—The American Red Cross Society has begun its work in behalf of the sufferers from the famine in India. The work for the present is merely preliminary and is in the direction of accumulating funds. As soon as a sufficient amount of money has been received, the Red Cross agents will be sent to India. The plan of relief will be the same as that so successfully operated in Cuba, where the Red Cross Society assumed the responsibility of ameliorating the wretched conditions of the starving reconcentrados Men and women will not be gratuitously supplied with food and clothing. Work will be demanded of them, and the society will make an effort to have the farms again worked and return persons to their chosen paths of trade and industry.

Sterility in Man.—E. Ries has made a study of sterility in the male, paying special attention to azoospermia due to obstruction in the system of sperm channels. He makes two classes of cases, according to the presence or absence of changes in the cellular tissue surrounding the seminiferous tubules. The most marked of these changes is the formation of a zone of hyaline tissue around the seminiferous tubules in the place of the normal flat connective-tissue cells which form the physiological sheath of the tubules. This zone of hyaline tissue cuts off the epithelium from its supply of nourishment, normally derived from the blood-vessels of the intertubular connective tissue. Degenerative changes of the epithelium accompany the formation of the hyaline rings. Where the hyaline zone is thin we find the epithelium of the tubule either normal, even containing spermatozoa, or the spermatozoa are absent and we find only a few layers of epithelium, or even only one layer, the border-lines between the cells frequently becoming indistinct. There is, however, a distinct cavity of the tubule, which is sometimes filled with spermatozoa. With the further encroachment of the hyaline zone, the epithelium is reduced to a very thin, flat layer, resembling endothelium, and these tubules contain nothing but a few fragments of cells. In the most pronounced cases the lumen of the tubule disappears completely, and instead of a channel lined with epithelium nothing is seen but a more or less wavy and hyaline mass of tissue with very few nuclei, without any trace of the normal testicular epithelium.—*Medical Times and Hospital Gazette*, September 1, 1900.

Improved Temperance Conditions in Manila.—Some time ago an ex-chaplain of volunteers, with that thirst for intemperate statements which many of his cloth and an occasional international medical orator seem possessed of, upon returning from the Philippines made the startling assertion that one of the results of American occupation had been an increase of saloons from four to more than four hundred. Every one who knew anything of the improved conditions in Manila, and who remembered the fate of the many other false statements regarding American rule there, was convinced of the incorrectness of this assertion, but the proof of its falsity was lacking. The report of the chaplain's rash statement got back to Manila, and, as we learn from the *Army and Navy Journal*, was commented upon by the *Manila Freedom* of April 21st, as follows: "We have taken some pains to investigate this charge, and have to say that it is false in every sense. When the flag was first planted in Manila there were between 4,000 and 5,000 grocery shacks, kept by Chinos and Filipinos, and every one

of them sold liquors, a native product, which did more to fill graves than disease and bullets. They were not saloons, but grog-shops, insidious hell-holes, and many soldiers became victims of them. Vino and other native drinks could be purchased for one cent a drink, American money, and ten cents was a sufficient sum for a common drunk and a penny or two more for a bacchanalian revel. Governor-General Otis had this problem to solve during the early days of occupation, and he was happily successful in closing most of the Chino and native shacks. A license system was established and the American saloon took the place of the native saloon. With their establishment the death and insane rates have been less, and the greatest good to the great number has thus been subserved. Instead of over four thousand places where liquors were sold we now have less than four hundred, and the quality of the stuff is vastly better and the quantity less. The insidious effects of vino and native gin soon alarmed physicians and surgeons, and an order was issued to seize and destroy all of said products found. This practically eliminated their manufacture, and to get them is as difficult as it is to get liquors in the veriest prohibition town of Kansas. Hail the reform!"

The Age of the Earth.—At the meeting of the British Association, which opened at Bradford, Yorkshire, on Wednesday, September 5th, one of the most engrossing addresses delivered was that by Professor W. J. Sollas treating of the age of this sphere. Leaving the nebular origin of the world to astronomers, Professor Sollas accepted "the infant earth from their hands as a molten globe ready made, its birth from a gaseous nebula duly certified." "In its early days," he said, "our planet was profoundly disturbed by tides, produced by the sun, for as yet there was no moon, and it has been suggested that one of its tidal waves rose to a height so great as to sever its connection with the earth and to fly off as the infant moon. This event may be regarded as marking the first critical period, or catastrophe if we please, in the history of our planet. The career of our satellite after its escape from the earth is not known till it attained a distance of nine terrestrial radii; after this its progress can be clearly followed. At the eventful time of parturition the earth was rotating, with a period of from two to four hours, about an axis inclined at some eleven degrees or twelve degrees to the ecliptic. The time which has elapsed since the moon occupied a position nine terrestrial radii distant from the earth, is at least fifty-six to fifty-seven million of years, but may have been much more. The solidification of the earth probably became completed soon after the birth of the moon. The temperature of its surface at the time of solidification was about 1,170° C., and it was, therefore, still surrounded by its primitive deep atmosphere of steam and other gases. This was the second critical period in the history of the earth, the stage of the consistentive status, the date of which Lord Kelvin would rather know than that of the Norman conquest, though he thinks it lies between twenty and forty millions of years ago, probably nearer twenty than forty."

Maternal Impressions.—Maternal impressions is a subject to which every pregnant woman should give both thought and consideration. Impressions of an unpleasant nature made upon a pregnant woman may cause mental and bodily effects in her child. It does not follow that the cause or object producing any shock to a woman will be photographed upon the unborn child, but the whole system suffers from the unpleasant impression made upon the mother. The consequence is a disastrous effect upon her offspring. It is only in the very early months of pregnancy that a shock can produce malformation of the child, but at any stage an unpleasant mental impression may produce "marks." Because so many defects in children are traceable to maternal impression, a wise woman will avoid every emotional disturbance during the months of pregnancy. A shock due to accident, and consequently unavoidable, should be dismissed from the mind immediately and never spoken of afterward. During the last siege of Paris, a very large percentage of children born were mentally and physically weak, while many others were imbecile or idiotic.—Dr. James Kiernan.

Controlling Thirst.—There has been recently much discussion in the London *Times* on this subject, and some of the correspondence has been of a highly interesting nature. The following is one of the letters sent to the *British Journal:* "The habit of drinking even cold water is one which is easily kept in the limits of the actual necessity of the body for renewing its moisture. But the habit must be regulated by the exercise of a certain self-control before the necessity arises. When I was a boy I had the ambition of exploration, and prepared myself by abstinence for privation. I used to abstain from drinking any liquid whatever for twenty-four hours at a time, knowing that thirst was the hardship most to be dreaded. I found the habit so acquired of great utility in my travels, and especially in the campaigns in Montenegro, which is a country of few wells and no springs, the main supply being rain-water collected in cisterns, and during the Turkish invasion their army could never maintain a force sufficient to hold the localities occupied, for the want of water. I have seen the Montenegrin army on a forced march almost uncontrollable from thirst, and my groom lie down in the road to drink from the puddles after a passing shower, though the water was yellow from the trampling of horse and man, while I felt no inconvenience whatever. I have seen the soldiers drink the entire contents of a cistern, such as is provided by the way at convenient distances, down to the mud at the bottom, as long as there was any liquid, huddling, crawling, almost fighting to get to the cistern, though I had made the same march (though on horseback) without the sensation of thirst. In the hottest weather of an Athenian or Italian summer, I have rarely drunk anything between meals, and avoid iced water as the greatest provocative of thirst."

Venesection and Saline Transfusion.—In the *Archives provinciales de Médecine* Raynaud has just concluded a serial article. The following is the author's own résumé: 1. Venesection by its depletive and depurative action is certainly the best method of mechanical disintoxication in all cases which represent a severe blood intoxication. It is not to be used as a routine procedure but only in emergencies, and its beneficial effect is only temporary. 2. Saline injections should be used only hypodermically. Thus employed they present none of the drawbacks of intravenous injections, although their action is somewhat less rapid. 3. Massive doses of saline solution may be employed in the treatment of medical hemorrhages, in algid collapse, in the ataxo-adynamia of typhoid affections, and in dysentery; but this remedy must always be used with discretion and with due regard to the state of the heart and kidneys. There are cases recorded of death due to the intemperate exhibition of saline transfusion. 4. Small fractional doses, as well as enemata of cold saline solution, may be used without fear in infections and intoxications, especially when there is vascular hypotension or difficulty in the action of the emunctories. It should be exhibited systematically from the onset of the disease in moderate quantities (150 to 500 c.c. daily). The general course and duration of the

disease are often very favorably modified. 5. In all severe toxæmias or infections, when the patient's circumstances are desperate, venesection followed by massive injections without renouncing other methods of treatment is often capable of rendering the greatest services and even of saving life. One should not wait until the last moment before exhibiting the solution. 6. When the patient is too far gone for phlebotomy, it is still possible to withdraw blood and inject saline solution at the same time and in equal quantities, this procedure being a safe one.

A Return to the Aboriginal Type.—Nearly every summer, after interest in the sea-serpent begins to flag, some scientist announces that Americans are approximating in facial conformation to the noble red man. Professor Starr, of Chicago, if the daily papers are to be believed, has the floor this year, saying that he has carefully measured the faces of more than five thousand children of Pennsylvania Dutch parentage, and has found in most cases "lengthening of the face and broadening of the cheek-bones in accordance with the characteristic features of Indian races."

The Human Eye and How to Care for It.—Dr. Reik, writing in the *Cosmopolitan* for September, says that the excessive use of alcohol and tobacco affects the eyes very seriously and that for some people tobacco is a poison and produces a lesion in the nerve of the eye leading to blindness. The most important thing of all, however, in order to take care of the sight is to get sufficient light to work and read by. The most desirable location of a light to read by is from above, behind, and to the left of the body. Of artificial lights the incandescent electric is the best, though the use of incandescent mantles has much improved gaslight. Where coal oil is the only illuminant the so-called student lamps make a very satisfactory light.

An Anti-Fat Town.—"The little town of Neodesha, Kan., claims a remarkable distinction. It has a population of fifteen hundred, and it is claimed that there are more thin people living there than in any place of similar size in the United States, many of its men and women weighing less than one hundred pounds, although in perfect health. Physicians explain that the Neodesha petroleum and natural gas wells are responsible for that condition, and that these elements are nature's anti-fat remedy. It is said that if the thin people of the town were dressed in the garb of the East Indian and stood up in line they would present a picture similar to that of 'starving India.'" We hasten to remark that our esteemed contemporary the New York *Times* is responsible for the above item. We simply quote but do not indorse.

Burial Weddings.—The Karens of Upper Burma not only delay their weddings till they can celebrate twenty or thirty at once, but make the same occasion serve for their funerals as well. When a man dies his body is cremated, and the ashes are kept until the time for the formal funeral. When a bad harvest or a prolonged rainy season occasions the need of a little excitement, and some enthusiast arranges a burial wedding, the ashes are arranged along a low, narrow platform, while the men stand on one side, the women on the other. There are no mourners, for the dead men have been forgotten during the convenient interval, and the dresses suggest only the pleasanter side of the double function. Proceedings are commenced by a sort of poetic competition between the men and the fairest maid. If the latter is not satisfied with the compliments paid her, she avoids the embarrassment of a direct refusal by bidding her suitor come for her "before he is awake." In this case he consoles himself with a pipe, and after a short interval transfers his addresses to some less exacting lady. As soon as the young people are equally paired off the elders compete for the more valuable portion of the dead man's property. Jewels or weapons are set swinging by a string while the claimants pass in single file. The one who is nearest when the pendulum stops swinging secures whatever is attached to it. When each has thus secured a memento of the day, the rest is handed over to the children, to be smashed up with all the crockery of the deceased and buried with their ashes on some neighboring hill.—*Answers.*

Plea for Consumptive Poor.—Dr. S. A. Knopf, writing to the Sunday *Tribune*, says: "There is an urgent need for a large city hospital for the exclusive treatment of the consumptive poor. Hospitals supported by private contributions will very rarely take a tuberculous case. The few existing institutions which receive consumptives can scarcely accommodate five hundred of these invalids. What becomes of the rest? Those who desire to know I would advise to visit a few of these sufferers in their tenement homes. The visitor will see more misery caused by this one disease than by all the others combined. In dingy, dark rooms the poor consumptive lives, often without medical attendance, but nearly always without proper food and supply of fresh air, so essential in combating this disease. Some faithful member of the family remains at home to nurse the sufferer, and in the majority of cases contracts the disease as a result of this devotion. We will see the faithful wife nursing a consumptive husband in the last stages of the disease, and on examining her we will discover that she suffers already from incipient tuberculosis. If there are children, they too may fall victims to the malady, owing to the ignorance or carelessness of the sufferer, and to the receptivity to disease of badly housed and underfed humanity. Yet could we take this invalid hopelessly ill away from the dreary tenement home to a special hospital, where he could be made comfortable, we would do away with a centre of infection which constantly endangers the lives of his own family, neighbors, and friends, and thus indirectly save, perhaps, many valuable lives."

Oysters and Disease.—In their small volume on "Oysters and Disease," Profs. W. A. Herdman and Robert Boyce record the results of an investigation extending over a period of three years, and although they have not actually established a connection between oysters and disease, they have produced the most important contribution which has yet appeared on the subject, which is one of considerable scientific and unusual popular interest. The disputed question as to the cause of green oysters has been re-examined with the result that several forms of greenness have been recognized and studied. But little is added to our knowledge of the well-known oysters of Marennes, the authors being in practical accord with most previous investigators, but concerning green oysters of Falmouth and certain green American oysters laid down in the vicinity of Liverpool, they reach results divergent from the views held by previous workers, and more in accord with popular belief. Copper in minute quantities is normally present in all oysters, but in the green Falmouths and Liverpool Americans is found in unusual amount. In the greenest of the American oysters as compared with the whitest, the proportion is 3.75 : 1 calculated for oysters, and 3.63 : 1 calculated on the ash, and a careful study of the distribution of the copper by chemical and histo-chemical methods demonstrates that it is the cause of the greenness. . . . The connection of oysters with the transmission of infectious diseases, especially typhoid

and enteric fever, is carefully considered. Bacilli of the colon group are frequently found in oysters sold in towns, but there is no evidence that they occur in those living in pure sea water. The experiments show that pure sea water is inimical to the growth of typhoid bacilli, and they do not multiply either in the alimentary tract or in the tissues of the living oyster. Bacillus typhosus was not found in any of the oysters obtained directly from dealers or directly from the sea, but from inoculated specimens the bacilli were obtained up to the tenth day, although the results indicate that they perish during passage through the intestines. Oysters and other mollusca obtained from dealers frequently contain a bacillus presumptively resulting from sewage contamination, but it was found that the infected oysters could be cleansed by washing in clear running sea water. It is evident, therefore, that by changing oysters from an infected bed to one where the surroundings are pure, they may be purged of their dangerous qualities.—*Science.*

Wounded in China.—The London *Medical Press* announces that the Grand Ducal government of Baden has decided to grant the use of their bathing establishments with all their therapeutic appliances to officers and soldiers of the allied forces wounded in China, free of all cost. Baden-Baden with its mild climate and efficacious mineral water and magnificent bathing establishments did such good service to the sick and wounded after the Franco-German war that we can only hope that the combatants of all nations will now make use of them with the same excellent results.

England's Coming Census.—When the results of the last census became known, the fact that the population of England and Wales fell short of the official estimates by nearly three-fourths of a million, created quite a sensation, but the random charges of inaccuracy were not substantiated. England and Wales were shown to contain 20,002,525 inhabitants; Scotland 4,025,647, and Ireland 4,704,750, making 37,732,922, the total for the United Kingdom. What increase is the forthcoming census likely to establish? According to the registrar-general's estimate, the population of England and Wales in July of the present year amounted to 32,091,907; Scotland, 4,313,993; and Ireland, 4,515,471, representing an aggregate of 40,921,371 for the United Kingdom. Seeing that the natural increase of the population amounts to 112,712 every three months, the census of 1901 may be expected to demonstrate that Great Britain and Ireland contain no fewer than 41,259,507 people, an advance of 3,526,585 since the census of 1891.—*Tribune.*

The Hygiene of High Altitudes.—*The Lancet* says: "It is well known that the chemical composition of the atmosphere differs little, if at all, wherever the sample be taken; whether it be on the high Alps or at the surface of the sea, the relation of oxygen to nitrogen and other constituents is the same. The favorable effects, therefore, of a change of air are not to be explained by any difference in the proportion of its gaseous constituents. One important difference, however, is the bacteriological one. The air of high altitudes contains no microbes, and is, in fact, sterile, whilst near the ground and some one hundred feet above it microbes are abundant. In the air of towns and crowded places, not only does the microbic impurity increase, but other impurities, such as the products of combustion of coal, accrue also. Several investigators have found traces of hydrogen and certain hydrocarbons in the air, and especially in the air of pine, oak, and birch forests. It is to these bodies, doubtless, consisting of traces of essential oils, to which the curative effects of certain health resorts are ascribed. Thus the locality of a fir forest is said to give relief in diseases of the respiratory tract. But all the same these traces of essential oil and aromatic products must be counted, strictly speaking, as impurities, since they are not apparently necessary constituents of the air. As recent analyses have shown, these bodies tend to disappear in the air as a higher altitude is reached, until they disappear altogether. It would seem, therefore, that microbes, hydrocarbons, and entities other than oxygen and nitrogen, and, perhaps we should add, argon, are only incidental to the neighborhood of human industry, animal life, damp, and vegetation."

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

PUERPERAL SEPSIS: ITS PATHOLOGY AND TREATMENT.[1]

BY WILLIAM R. PRYOR, M.D.,

NEW YORK.

IT is hardly possible that in the time allotted me I can give a description of the many and minute changes wrought in the system by puerperal sepsis or discuss all the various methods of treatment. Still, I can call your attention to certain of the more recent investigations into the pathogenesis of puerperal sepsis and perhaps bring out a discussion regarding treatment which may be of value to us all.

The manner in which women become infected is of great interest. It is a comforting belief that auto-infection may take place, but the observations of Krönig and Whitridge Williams pretty thoroughly disprove the possibility of this except in very, very rare instances.

An infecting coitus may take place just previous to delivery, as well as may an infecting examination, but such is not auto-infection. About forty-nine per cent. of prostitutes have the gonococcus present though latent in the cervical glands, and a small percentage of honest married women have the same. In such of course self-infection by the gonococcus after delivery is possible. Lastly, a few women with a pus focus in one or the other adnexa will conceive and go to full term, and become infected by this after deliqery. But this must be exceedingly rare, because such a lesion supposes sterility or induces early abortion. We are therefore forced to believe that puerperal sepsis is caused by germs which are introduced from without.

Causes: Franz, the most recent writer on this subject, found the gonococcus present in but four per cent. of his fifty cases of puerperal fever: once in a mild case accompanied by saprophytes, and once in a severe case with streptococci. The degree of infection produced by the gonococcus is mild.

In three hundred cases of afebrile puerperia nine observers found some sort of germ in twenty-seven per cent., but never the streptococcus or pyogenic staphylococcus. In a very few cases of mild form streptococci are found, but in nearly all cases of infection by pyogenic streptococci and staphylococci the symptoms are grave. We are therefore warranted in asserting that puerperal sepsis is caused by streptococci and staphylococci. But in most cases these are accompanied by other germs, especially saprophytes.

Lesions produced: Upon entering the uterus these germs soon penetrate deep into the decidua through the endometrium and enter the lymph channels of the uterus. From there they pass into the venous sinuses and into the lymphatics of the pelvis, thus entering the general venous and lymphatic systems. The peritoneum over the uterus and lymphatics may become inflamed, pouring out serum, lymph, or pus. Septic emboli may break from the thrombi in the ovarian or iliac veins and produce septic infarcts elsewhere. Septic pneumonia, septic endocarditis, acute nephritis, and general suppurative peritonitis are some of the graver lesions induced, while ovarian abscess and pyosalpinx are local results. Viewed in the light of the lesions resulting we may divide puerperal sepsis into septic thrombosis and pelvic lymphangitis. We may also describe as puerperal any septic condition occurring after abortion when the induced lesions are such as we see follow full-term labor. The most rapidly fatal cases are thrombotic.

The havoc wrought by the infection is governed by a great many factors. Chief among these is the virulence of the infecting germs. Then the traumatism to which the uterus has been subjected, the patient's general condition, and the area of endometrium invaded, all influence the result.

Unlike saprophytic or putrid infection which tends to spontaneous recovery, puerperal sepsis if not rapidly fatal almost always produces lesions which seriously damage either a pelvic organ or other viscera. I wish this fact to be borne in mind when we consider the treatment. Time is here an important element. Therefore we are to consider not only the mortality figures but also the morbidity.

Regarding the virulence of the germs in different localities we notice that while Krönig and Whitridge Williams in their cases had a mortality of about five per cent., Edgar Macharg in fifty-seven cases had fifty-four per cent. mortality. And those who will recall the epidemic here of 1881 will remember the great number who died.

The danger from saprophytic infection being so slight and its correction so easy, while the danger from streptococcus infection is great and the best method of dealing with it in dispute, the importance of an accurate diagnosis is apparent.

The best way to secure uncontaminated the uterine lochia is by means of a Döderlein tube which is passed, after sterilization, into the uterus and without touching the vulva or vagina. Even here there is a leak in the technique, for the cervical glands may soil the tube, but will hardly get into the lochia which is sucked up from the fundal cavity.

Having found pyogenic cocci, how shall we proceed to treat the case? The most popular method of treatment is by intermittent washing. This is what Macharg did and lost fifty-four per cent. of his cases. Besides, the cocci not being on the surface but deep in the uterine walls, washing cannot and does not reach them. All it succeeds in doing is to increase the distress by inflicting additional and needless trauma. The gentlemen who laud washing have not made bacteriological examinations of their patients' discharges, and they can rest assured that when they see benefit from the treatment it is not in streptococcus cases but those of saprophytic nature. And even in these they have subjected their patients to needless danger by improperly performed manœuvres, for it is too easy to convert a saprophytic infection into a septic.

Curettage of the septic uterus gives a prohibitive mortality; and again we must condemn a measure in sepsis which is of benefit in saprophytic infection.

Serum therapy: The commission appointed by the

[1] Read before the New York State Medical Association, October 16, 1900.

American Gynæcological Society, of which I have the honor to be a member, reported in 1898 that Marmorek's serum when used in one hundred and one cases of streptococcus puerperal fever, gave a mortality of thirty-three per cent. Of course if used in cases showing no streptococci the mortality is less, but we do not believe the advocates of the serum claim it is efficacious against any germ but the streptococcus, and in streptococcus infection the mortality is thirty-three per cent. We found that the serum was used in two hundred and fifty-one cases in which no bacteriological diagnosis was made and gave a mortality of sixteen per cent. Now, as Williams found the streptococcus in but twenty-five per cent. of his cases of puerperal fever, Krönig in nineteen per cent. of his, Franz in twenty-six per cent. of his, we can assume that of these two hundred and fifty-one cases about one-quarter were streptococcic; and, as the other seventy-five per cent. would have lived if let alone, the serum here was followed by forty deaths in sixty-three cases, or sixty-three per cent. morality. If we could only know the kind of streptococcus a given serum was prepared from and could secure a case infected by just that identical streptococcus we might secure better results from its use; but as our knowledge of streptococci now stands the administration of antistreptococcus serum is followed by a mortality which prohibits its use.

Fortunately in taking from the man who occasionally sees a case of puerperal fever this much-lauded remedy, we have other methods of treatment more efficacious to offer.

These septic cases are to be considered in two classes. The cases of thrombosis are comparatively rare. When the diagnosis can be made my belief is that no form of treatment will prove effective short of an abdominal hysterectomy, preceded by intravenous infusion, and rapidly performed. Inasmuch as here as well as in pure pelvic lymphangitis the peritoneum and lymph streams are invaded, I would suggest the use of a large abdominal Mikulicz iodoform-gauze dressing. But this is the only form of puerperal sepsis in which I would perform hysterectomy.

How are we to treat the more common cases of septic pelvic lymphangitis, the usual perperal sepsis?

Krönig, basing his practice upon fifty-six cases of sepsis, lost four per cent., employing a general supporting treatment only.

Whitridge Williams, in twenty-three cases treated in a similar manner, lost 4.35 per cent. So the general practitioner has good ground for refusing to listen to the gynæcologist when he advises operation. But I for one cannot forget the mortality which attended exactly the same treatment in olden days, emphasized as it is by Macharg's recent figures.

I must believe that the infecting germs in Williams and Krönig's cases were weak and not virulent. But though accepting all they say as to mortality, the unchecked sepsis must have wrought havoc not only with the pelvic organs but also with the general health.

I cannot see the logic of their position and must believe that these gentlemen, for whose scientific attainments I have the greatest respect, have been unduly attracted by the seductively low mortality. At the time that Williams reported his cases I gave a list of fourteen cases in which I had operated, one when the patient was dying with endocarditis and nephritis, with this one death. To show how completely these women recovered, two have since been reported as pregnant. The method I have adopted since 1894 has proceeded along these lines: I have attempted to check the local infection and to combat the general septicæmia. Incidentally also I wished to prevent pelvic suppuration.

I curette the uterus as thoroughly as possible, being careful to wash out all débris with this tube, using many quarts of decinormal salt solution. The material removed by the curette is placed in a sterile jar for examination. I then pack the uterus full of five-per-cent. iodoform gauze.

The next step is to make a broad incision into the posterior cul-de-sac. Through this I evacuate all fluids in the pelvis, saving a specimen for examination. In all cases there is much serum present, some lymph, and often pus free in the pelvis. Any false union between the organs is broken, and the pelvis is wiped dry. I now make what I call the pelvic Mikulicz dressing of iodoform gauze. This dressing completely fills all parts of the pelvis and is in close apposition to all the pelvic peritoneum to the pelvic brim, except in front of the uterus. The iodoform is soon broken up by the serum, and so rapid is its absorption that it appears in the urine from two to five hours after the operation. The circulation of so large an amount of this powerful antiseptic in the blood must have a deterrent effect upon the general sepsis, as these charts will show.

To determine whether the streptococci which I found in the uterus and in the pelvic cavity were destroyed, I instituted, with Dr. Jeffries, bacteriologist to several of our institutions, a series of investigations. We found that invariably all cocci were destroyed, streptococci remaining to the third dressing in only one patient, and she has reported pregnant.

If under ether I find the pulse 120 or over, or if there are grave visceral lesions elsewhere, particularly in the heart and kidneys, I always do an intravenous saline infusion of from two to three quarts. This seems a severe measure, but all the cases brought to me are in bad shape and most of them have nephritis.

The essence of the treatment is local and general iodism, together with promotion of the function of the kidneys. After the operation I use colon enemata of salt solution every three hours, for the purpose of eliminating the toxins and the iodine. This treatment has been employed over fifty times by myself and associates. By means of it I feel sure we have saved women who would otherwise have died. While the procedure is novel to some of you, and while it is based upon a new principle, namely, the introduction into the blood of so powerful an antiseptic as iodine which would appear dangerous, I cannot but be governed by what we have seen.

Such is the position of our present knowledge regarding puerperal sepsis. Repeated irrigations we find do harm. Curettage gives twenty per cent. mortality. Serum therapy gives thirty-three per cent. mortality. We have coming from great men the conclusion that it is best to do nothing in an operative way. You may elect to accept that advice. But what will you do if their further experience prompts them to desert you? If you are now so disposed as to follow me and many others, perform a rapid abdominal hysterectomy in your cases of thrombosis, and in the cases of true puerperal sepsis the curettage and cul-de-sac operation as I have described it.

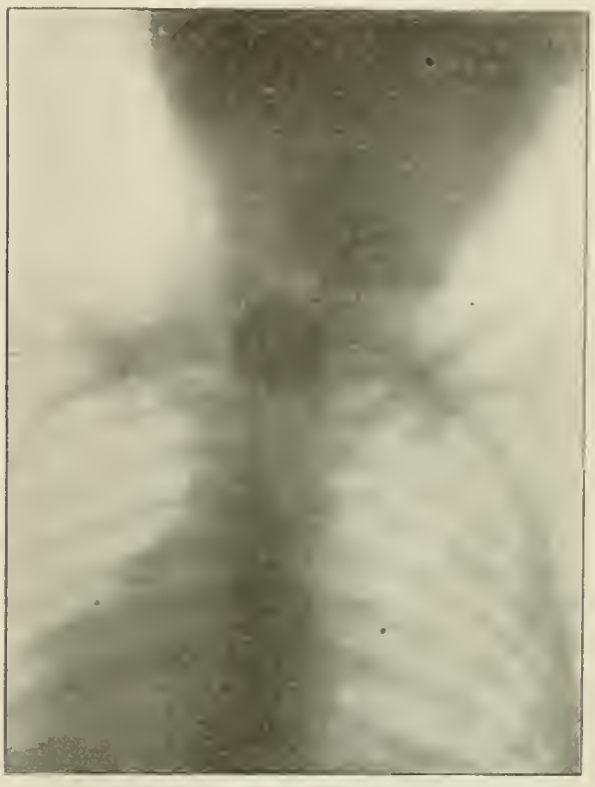
An Enormous Fibroma of the Fundus Uteri.—A. Pinna Pintor removed this new growth through an incision extending from the symphysis to two inches above the umbilicus. The tumor was closely adherent to the surrounding parts, but was successfully removed and the attempt made to save the uterus. Owing to the hemorrhage this was impossible and amputation had to be done. The tumor which had been first noticed by the patient three years previously was found to weigh twenty-six and one-half pounds and to measure forty-eight inches in circumference.—*Centralblatt für Gynäkologie*, September 15, 1900.

FOREIGN BODIES IN THE ŒSOPHAGUS.[1]

By GEORGE W. KING, M.D.,

HELENA, MONT.

The clinical history of a recent case of impaction of a foreign body in the œsophagus is herewith submitted for the purpose of illustrating in a practical way the principal points to be considered in the diagnosis and treatment of this accident. A girl aged six years, while amusing herself with a penny whistle, inadvertently allowed it to slip backward into the pharynx, and becoming alarmed she made violent efforts at swallowing, which forced the body onward into the œsophagus and beyond reach of the finger. Several copious draughts of water were taken, but served no useful purpose in accelerating the progress of the whistle downward. She then informed her mother of the accident. Nothing was done, however, until the following day when she was presented for examination with the above history. During the night several attacks of vomiting had occurred without effecting dislodgment or expulsion of the foreign body. Fluids could be swallowed without regurgitation. Some degree of discomfort existed, pain over the sternum and cervical region being the most prominent symptom complained of. Respiration appeared to be normal. No information concerning the presence or position of the whistle could be gathered by palpation or superficial examination. The absence of urgent symptoms suggested the probability that passage downward had been successfully accomplished during the interval. The traumatism produced by the passage of a body of that size would account for the irritation present. Fortunately we are no longer compelled to remain in doubt when dealing with this class of cases. The fluoroscope and skiagraph demonstrate clearly what we desire to know without subjecting our patients to the annoyance incident to the use of sounds or other instruments, which after all are liable to fail in the object for which they are employed. The accompanying illustration made from a skiagraph indicates the utility of this method of examination. The vertical position of the whistle is well shown, but its exact location when measured by fractions of an inch is largely a matter of conjecture. The position and distance of the Crookes tube in relation to the object and the diffusibility of the rays must be carefully noted in order to eliminate errors in the interpretation of the shadow. Facility in this respect is acquired by experience in this line of work. In this instance the picture represents the object as slightly below its actual position. This difference was immaterial, inasmuch as there was positive assurance that the impaction was in the cervical portion of the œsophagus and therefore accessible, and this furnished sufficient data for all practical purposes. The patient was put under an anæsthetic and extraction by the mouth was undertaken. It was found to be impossible to locate and grasp the foreign body with suitable instruments; sounds or bougies failed to give evidence of contact, apparently passing by the seat of obstruction without impinging upon the rim of the whistle. It soon became evident that nothing could be accomplished by this route and the operation was for the time abandoned. Considerable reaction followed, the temperature went up to 102° F., and there were marked symptoms of acute bronchitis, induced in all probability by exposure or traumatism. Appropriate remedies were prescribed and the patient was left undisturbed until her condition would justify further operative interference. With the subsidence of the bronchitis a more distressing condition developed, viz., spasm of the glottis accompanied by an incessant cough, reflex in character, caused by the presence of the foreign body. Œsophagotomy being the only operation likely to afford relief, it was performed without incident. The incision was made in the usual location, *i.e.*, upon the left side along the anterior border of the sterno-mastoid muscle, the fascia was divided with due regard to the position of the vessels and nerves lying within the field of operation, the tissues were carefully separated by blunt dissection until the bodies of the cervical vertebræ could be felt with the finger, the carotid sheath was retracted outward, and the trachea and thyroid gland were rotated in the opposite direction. A sound was now introduced into the œsophagus and two silk sutures were placed in appropriate position in its walls, and the ends were



left long to facilitate control of the part during the subsequent manipulations. The tube was opened over the point of the sound and the latter was withdrawn. A forceps was passed downward through the incision to the depth of six inches and upward to nearly the same distance without encountering the foreign body. A metallic bougie-à-boule was then substituted, and being introduced came directly in contact with the whistle which was embedded just below the cricoid cartilage. A small instrument was passed under the rim, and by a prying motion the whistle was loosened and forced upward and outward where it could be easily grasped with the forceps and extracted. It is worthy of remark that the same instrument by means of which the whistle was located through the incision had been passed by the mouth in the previous attempt with negative result. The incision in the œsophagus was closed by absorbable sutures and the lower angle of the wound external to it was loosely packed. The head was fixed by a pasteboard splint extending upward from the dorsal region. No vessel of sufficient size to require a ligature was divided during the operation; hemorrhage therefore was limited to slight oozing. No injury to the nerves resulted. In the after-treatment nothing was given by the mouth until the fifth day, nutrient enemata being used to sustain the patient. The wound remained free from infection and the healing progressed satisfactorily.

A small fistulous opening, through which there was an occasional escape of food, remained for a time, but

[1] Read at the meeting of the Rocky Mountain Interstate Medical Association, August 29, 1900, at Butte, Mont.

did not cause any special inconvenience. The patient was discharged one month from the date of operation. The whistle measured one inch in diameter, and had been impacted for ten days.

The favorable issue in this case was due to the smooth surface and accessible location of the foreign body, permitting its removal without laceration of the tissues, and last but not least, the absence of infection of the wounded surfaces. This latter complication cannot be effectually guarded against, owing to the impossibility of maintaining accurate apposition of the edges of the incision until union has been accomplished. The involuntary act of deglutition will sooner or later cause one or more of the stitches to cut through, with subsequent separation of the line of union. For this reason some operators omit sutures altogether, preferring an open wound to a partially closed one. Theoretically, approximation by suture with fixation of the head, nothing being taken by the mouth for the first week, ought to give the best results.

External œsophagotomy for the removal of foreign bodies is not an operation of recent date. Suggested by Verdu in 1643, first performed by Goursald in 1738, it has long been recognized as a legitimate operation when indicated, yet up to 1894 there were but one hundred and thirty-five recorded cases, mostly the work of German surgeons. In the one hundred and thirty-five cases there were one hundred recoveries. The mortality rate is influenced by certain conditions here as elsewhere; thus, late operations show an increased death rate over the early, other conditions being equal, and again the situation and nature of the foreign body are important factors in determining the result.

If we study the anatomical relations of the œsophagus in the cervical region with special reference to the operation of œsophagotomy, we shall find that the space to be invaded is occupied in part by the left lobe of the thyroid gland, the left common carotid artery, the inferior thyroid artery, the middle and superior thyroid veins, the left recurrent laryngeal nerve, and the omohyoid muscle. The trachea, from its position and intimate relation to the tube, may be regarded as within the danger limit. Injury to the recurrent laryngeal nerve, opening the trachea by mistake or otherwise, wounding the carotid artery, are among the accidents that might happen to experienced operators as well as to the novice. Conditions which add to the difficulty of the operation are chiefly swelling or enlargement of the glands in the cervical region, unusual depth of the œsophagus, and failure to find the foreign body or when located to loosen it from the point at which it is embedded. The causes of death following the operation are for the most part septicæmia and exhaustion.

The œsophagus in its descent through the thorax is never isolated from important structures; the transverse portion of the arch of the aorta, the left bronchus, the pericardium, a part of the descending aorta, the thoracic duct, and the pneumogastric nerves, are in contact with or in close relation to the tube at certain points in its course, and consequently are liable to injury by retention of a foreign body or by undue violence in the passage of instruments.

The predisposition of the œsophagus to the lodgment of foreign bodies is due to normal constrictions which exist in three places, viz., at the cricoid cartilage, at the bifurcation of the bronchi (about the level of the first rib), and at the diaphragmatic opening. Large or rounded bodies are usually arrested at the cricoid narrowing, by reason of the unyielding larynx in front and the bodies of the cervical vertebræ behind, which serve to limit dilatation in the anteroposterior direction. Oblong and smaller objects may pass on to the second or third constriction and be there retained.

In view of the manifold dangers and difficulties to be encountered, the removal of foreign bodies lodged in the œsophagus cannot be regarded as a trivial operation. When undertaken with no conception of its gravity and without an accurate knowledge of the anatomical relations above detailed, the risk to the patient exceeds that of many operations of greater magnitude. Too energetic and ill-directed efforts are most likely to fail and in addition to inflict irreparable injury. No rules can be laid down for the treatment of those cases of large impaction in the pharynx when suffocation is imminent. Here the choice of adequate instruments and the presence of the skilled hand to direct them must yield to the greater urgency of immediate action. The finger is always available and should be unhesitatingly employed, as should also inversion of the patient. No technical skill is exercised in these acts, yet it is what the skilful surgeon himself would do under similar circumstances. It is true the latter has other resources at command, but this does not imply that simple and common-sense methods should be overlooked in any case. The size, shape, consistency, and location of the object must be taken into consideration in forming a proper estimate of the difficulties to be overcome in the process of extraction. The diagnosis can be made with certainty by the use of the *x*-ray, the exceptions being few and unimportant so far as the treatment is concerned. (Reference is here made to impactions which consist entirely of alimentary substances that cannot be skiagraphed.) The retention of bodies which are uniform in shape with smooth rounded exterior, is naturally attended with less danger than that of bodies presenting irregular outlines, with sharp cutting edges or points which easily pierce the tissues and in some situations might wound important organs and produce a fatal result. It is obvious that in the latter case attempts at withdrawal or propulsion could not be made without more or less laceration of the tube, even in the most careful hands. This fact should emphasize the importance of a careful study of conditions before resort to the use of instruments, and also the avoidance of brute force when it becomes necessary to employ them. The cervical portion of the œsophagus lies within reach of instruments passed by the mouth, and removal of the impacted body may often be effected by this route. This is the method almost universally employed and is the operation of choice, and if conducted with a reasonable amount of skill it ought not to result in harm to the patient. Too violent or long-continued efforts are not advisable, since we have in œsophagotomy a more surgical procedure which may be relied upon to succeed within proper limits. The incision renders the part more accessible —a decided advantage duly appreciated by those who have had occasion to resort to the operation.

The administration of an anæsthetic as a preliminary to the introduction of instruments by the mouth is seldom required in the case of adults, but when we are dealing with children it becomes indispensable. The patient should then be put in the Roser position to lessen the danger of suffocation and at the same time facilitate the passage of sounds or bougies by straightening out the folds in the œsophagus. In the search after and removal of foreign bodies impacted in the œsophagus, the danger and difficulty increase with the depth, for the point of an instrument passed by the mouth into the thoracic portion of the tube is practically beyond the control of the operator and in spite of the utmost care rupture and injury to adjacent organs are among the possibilities. The flexible œsophageal forceps can be introduced to any depth desired, but its grasp is not firm enough to hold an

object which requires considerable force in withdrawal. The failure to extract from above by use of the finger or instruments passed by the mouth, by inversion of the patient, or by emesis when applicable, limits the choice of further interference to incision; by that I mean œsophagotomy or gastrotomy, one or both combined, or to propulsion, *i.e.*, forcing the impacted body on into the stomach. The latter is to be preferred when feasible, and moreover has the merit of having been known to succeed in numerous instances. In suitable cases, then, this method should be employed, but we must keep in mind the chances of error arising from the fact that a sound or bougie may glide past the object without giving evidence of contact, the impression being conveyed that the tube is clear and requires no further attention. It must be admitted that propulsion is not entitled to very high rank by reason of its uncertainty in results and its manifest limitations. It is permissible only when the foreign body is known to be smooth and uniform in shape or composed of an alimentary bolus which can be safely forced through the passage. Extraction by incision or other means is undoubtedly the correct treatment for foreign bodies in the œsophagus. At times it is easy of accomplishment, but oftener it taxes the ingenuity and resources of the operator even though he be possessed of more than average skill, and it is not surprising therefore that the expectant plan should be adopted by many and that the foreign body should be left to itself when situated low down in the thoracic portion of the œsophagus. Such practice may be open to criticism, yet it is not without precedent, its justification resting upon the absolute failure of extraction or propulsion.

REPORT OF THREE CASES OF INTESTINAL OBSTRUCTION DUE TO MECKEL'S DIVERTICULA.[1]

JOHN F. ERDMANN, M.D.,

NEW YORK,

CLINICAL PROFESSOR OF SURGERY IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

In presenting this report no attempt at any scientific consideration of the subject will be made. The author was struck by the coincidence of three of these rare cases coming under his observation within a period of five and a half months, and deemed the citation of the histories of the cases of sufficient importance, from a clinical standpoint, to prove of interest to the members of this association. A feature of these cases was the pronounced resemblance, from a clinical standpoint, to appendicular involvement; another feature was that in each of two of the cases there was an existing appendicular complication.

I confess that in each of these two cases the diagnosis of appendicitis was made, although in one of them doubt as to the diagnosis was expressed and exploration was suggested; while in the first of the cases recorded I was undecided between acute obstruction by internal strangulation and perforative appendicitis of the so-called fulminating variety. Close study of the symptomatology of these cases will readily demonstrate the resemblance to three varieties of symptoms of onset in appendicitis, namely, the first the so-called acute fulminating or profoundly septic, the second a subacute attack attended by abscess formation, and the third an acute appendicitis accompanied by gangrene with toxic absorption.

In the first case, the symptoms were due entirely to a rapid strangulation, with gangrene of seven feet of bowel and rapid sepsis; in the second case, the symptoms were produced both by the involvement of the appendix and a partial strangulation of some five feet of bowel, with gangrene of the diverticulum; while in the third case the symptoms were due to acute appendicitis and a gangrenous adherent diverticulum, with no gut inclusion except through the medium of bands of adhesions of some former trouble.

[1] Read before the State Medical Association, October 18, 1900.

Case I.—M. K——, gentleman rider of the Horse Show of 1899, was seen by the writer on November 15th at 10:30 A.M., exactly twenty-four hours from the date of onset of his illness, at which time the following history was obtained. He had been perfectly well up to November 14th, at 10:30 A.M. He said he had eaten a large quantity of white grapes on the day preceding. On the morning of November 14th he was seized with an attack of pain in the abdomen which he said was very severe and was accompanied by nausea and vomiting. At this time the hotel physician saw him and gave him several injections of morphine. Owing to the hotel physician being called out of town and his pain still persisting, Dr. John Woodman was called in the evening and found him suffering slightly from pain, the abdomen somewhat rigid, pulse, temperature, respirations practically normal; vomiting and nausea still present. Dr. Woodman saw him early the next morning, at which time the symptom complex presented such a grave aspect that a consultation with a surgeon was advised. I saw the patient at 10:30 A.M., exactly twenty-four hours after the onset of pain; at this time there were all the manifestations of an acute abdominal involvement; his face was pinched and anxious, somewhat livid or cyanotic, pulse 144–150, respirations rapid and shallow; the temperature was not taken; the abdomen was distended and exceptionally sensitive—in fact, painful to the touch; rigidity of the abdominal muscles was more marked on the right side, and pain also was more evident on this side. He had just vomited some greenish material. There had been no evacuation of fæces by the bowel and no flatus had passed in twenty-four hours. An exploratory section was suggested, and the patient transferred to the St. Mark's Hospital. The operation was performed at 12:15 P.M., twenty-six and one-quarter hours after the onset. Upon opening the abdomen through the right rectus I found the peritoneal cavity filled with offensive bloody fluid and a large mass of gangrenous small intestine; at the points between healthy and gangrenous bowel I found a band surrounding the bowel. This proved to be a Meckel's diverticulum with its distal end attached to the umbilicus and its proximal end within three feet of the ileo-cæcal junction. The patient's condition was such that nothing further than liberating the strangulation and excluding the gangrenous gut from the abdomen was done. Although the patient stood the operation badly, he reacted within three hours in a most gratifying manner, with absolute freedom from pain, nausea, and vomiting, and a well-marked improvement in his pulse. This condition of improvement continued until the following morning at seven o'clock, when he became rapidly toxic and died within an hour. There were exactly seven feet of gangrenous gut removed upon autopsy.

Case II.—Previously reported, with presentation of the patient and specimen to the Surgical Society of New York City. E. D——, twenty years old, clerk, was seen by me with Dr. S. Leo, on March 1, 1900, at which time the following history was obtained. On Wednesday, the last of February, about 2 P.M., and one and one-half hours after a lunch of roast-beef sandwich, cake, and coffee, he was seized with pain in the abdomen, not localized in any one region; "he broke out in a perspiration," and had two or three chills lasting in all about two hours. He vomited about four hours after the onset of pain. During these four hours his pain was constantly increasing. Pain was severe but not intensified throughout the night. He was

given some codeine by Dr. Leo. No movement of the bowel, except a small quantity passed as a result of an enema on Thursday, March 1st. I saw him March 1st, 8 P.M., at which time his pulse was 86–90; temperature, 100.5° F. The temperature had been 101.5° in the forenoon. Deep pressure elicited some pain in the abdomen, localized on the right side a little internal and superior to the usual appendicular situation. The right rectus was somewhat rigid. The urine contained no albumin; its quantity had not been measured, but the patient said he had been passing urine as frequently and in as large quantities as usual. He was taken off the codeine, given calomel internally, and ice used externally. Friday, March 2d, I saw him again with Dr. Leo. Temperature, 99.5° F.; pulse, 80–84; pain localized on the right side, not excessive; the rectus was tense, but not markedly so. There was some tympanites, not general, but rather outlining coils of intestines. Dr. Leo telephoned Saturday, March 3d, that the patient's condition had become normal, and that my services were not necessary; that there was a very slight amount of pain remaining on deep pressure. Sunday night, March 4th, I was telephoned that his condition had again become grave, and made an appointment for the following morning, at which time I was told that he had vomited fecal material Saturday evening twice and once Sunday morning, and that there had been a large evacuation per rectum following the introduction of an enema. When I saw him Monday morning, at 10:30, his condition was one of anxiety, his face was drawn; pulse, 118; temperature, 101.5° F.; abdomen generally tympanitic, pain in the right side and in the umbilical and hypogastric regions. Operation was advised and accepted. Dr. C. Leale was present, by the family's request, at the operation.

An incision was made in the usual manner for appendicitis. When the peritoneum was incised, a large quantity of dark-brown fluid was evacuated and a coil of deeply congested intestine was seen. The appendix was found bound down posterior to the cæcum and ascending colon, and several coproliths could be palpated. Many recent adhesions were also present. The examining finger palpated a dense band surrounding a mass of intestine. The incision was rapidly enlarged through the right rectus, and then a mass of intestine fully five feet long, dark brown and œdematous, was extruded, with a Meckel's diverticulum about three inches long, one-half inch in diameter at its base, and a long fibrous extension leading up to the umbilicus, literally tied about the involved intestine. One portion of the diverticulum was gangrenous and adherent to a coil of ileum. A small amount of pus was present at this situation. The intestinal end of the diverticulum was cut off, and the intestinal site of the diverticulum was inverted as in an appendix operation; a row of Lembert sutures was placed to strengthen the area. The umbilical end was cut after the application of a catgut ligature near the umbilicus. The appendix was next removed in the usual manner, its stump being inverted after the method of Dawbarn. Feeling that it would be rather risky to close the abdomen entirely, I placed a gauze drain at the site of the inverted stump of the appendix, and also one at the site of the removed diverticulum. The greater portion of the wound was then closed with three rows of catgut sutures and a superficial one of silk. A great amount of serous discharge was present the first twenty-four hours. Temperature and pulse became practically normal after the second day, from which time convalescence was rapid.

Case III. Male, J. L——, aged thirty-four years. Previous history negative. He was seen by the writer on May 1st, in consultation with Drs. Goldberger and Kompert at about midnight, and I obtained the following history. He was seized with a severe generalized pain in the abdomen on Sunday, April 29th; had neither chill nor had he vomited; on the day following, *i.e.*, April 30th, the pain was localized in the right iliac fossa, with evidences of a tumor. The rectus on the right was rigid, not marked on the left. When I saw him his pulse was 90; temperature, 101°; respiration, 22; abdomen somewhat distended, pain pronounced in the right side, and a tumor distinctly palpable. The rectus was somewhat rigid. I advised operation the following day. On the morning of May 2d, the day of operation, his pulse was 96; temperature, 102.6°; and respiration, 26. Under anæsthesia a mass could be outlined, that suggested a very much distended appendix, or one accompanied by a great deal of exudate. The abdomen having been prepared, an incision was made after the manner of Kammerer, etc., and a diverticulum about three and one-half inches by one and one-half inches wide, with a pronounced mesentery, was found adherent to the parietal peritoneum in the right iliac region; the apex of this was gangrenous and covered with considerable exudate; in addition, about six inches of bowel was partially strangulated by a band in the immediate vicinity. This latter was released, the diverticulum cut off, and the opening in the intestine closed with three tiers of suture. Search was then made for the appendix, which was found in a state of acute inflammation surrounded by a dense mass of adhesions. The appendix was removed by splitting the serosa and musculosa, thereby leaving only the mucosa; in other words, the appendix was stripped (a method I have often found of service in cases with dense adhesions, and one by which an immense amount of time is saved). The appendix was then removed, and the stump inverted after the method of Dawbarn. Several coproliths were found in the appendix. The abdomen was wiped out with gauze, a small wick drain was placed in the lower angle of the wound, and tier sutures were employed to close the remainder of the incision. The drainage was removed in forty-eight hours, and with the exception of a stitch abscess the recovery was uncomplicated.

Attention has been called in this paper to the resemblance of the onset in each of these cases to an attack of appendicitis; and when one remembers that the usual location of these diverticula is within three feet of the cæcum, no great amount of suggestion is necessary to show the effect symptomatically of an inflammation or involvement of a viscus in such proximity to the appendix. Naturally, the conditions of obstruction rapidly supervene upon those of sympathetic involvement, and thus the diagnosis of obstruction from some other cause than appendicitis is more readily made, except when profound sepsis is present, as was noted in the history of Case I.

Black Tongue.—A new case of this rare malady is reported by J. Maraval, whose patient was a man aged forty-two years, and an inveterate smoker. For two months he had complained of pharyngeal dysæsthesia, discomfort in movements of the tongue, sensation in swallowing as of a foreign body, and abundant salivation. Examination showed a brownish-yellow patch in the region of the circumvallate papillæ which could be peeled off in threads, and which under the microscope seemed to be made up of imbricated epithelium surrounding a central axis. The area of implantation was thoroughly curetted and a solution of zinc chloride 1:20 applied. He was seen six months later with practically the same condition. He had abstained from tobacco for four months after the curetting, during which time he remained well, but on resuming smoking the deposit reappeared.—*Revue Hebdomadaire de Laryngologie*, No. 36, 1900.

ELECTRIC LIGHT—ITS PHYSIOLOGICAL ACTION AND THERAPEUTIC VALUE IN TUBERCULOSIS OF THE THROAT AND LUNGS.[1]

By W. FREUDENTHAL, M.D.,

NEW YORK.

While in modern times we have quite a number of newly discovered drugs, some of which exert a remarkable effect on the human system, we have come to believe that bottles of medicine cannot cure every disease nor afford relief to many sufferings with which the physician is daily brought in contact. Thus we have come to rely upon resources which nature has placed at our command—the scientific application of water, hydrotherapy; the use of light and air, which is still an undeveloped science; and finally the use of electricity in its various branches. The latest of these is the action of the chemical rays of light upon the diseased human system.

We know that in the olden times, in Greece as well as in Rome, as protection against disease nothing was esteemed so highly as the sojourn in the open air. The sun and the air were considered of the greatest importance for the health and life of man and animal. The whole life of the ancients, as Julian Marcuse[2] rightly says, was built upon this basis, and public affairs, as well as athletic sports, brought the Grecians and Romans on the street and into the open air.

Light and air, the imponderable requisites of unimpaired bodily and mental health, were then the foundation of the physical and psychical well-being, which will always remain the characteristic sign of the classic ages. Not only were the bedrooms in old Greece open to the rays of light, but the houses had, as is well known, on their roofs what was called ἡλιαστήριον, a place where the inmates exposed their naked and anointed bodies to the sun, not only for pleasure, but for the preservation of their health as well.

In Rome this place on the roof, which was perfectly flat, was called solarium. Afterward this solarium was a special annex to the house. The white color of the skin of a man not browned by the sun was considered effeminate, and its possessor was ridiculed. That later on these prophylactic sun-baths were taken to cure disease is not remarkable; and in Rome there was hardly a bath-house without a solarium—that is, a place to take sun-baths.

In the Middle Ages these baths were neglected more and more, until up to the nineteenth century they were entirely forgotten.

It was a layman, Arnold Rikli, of Veldes, in Austria, who not long ago started the first institution for what he termed "atmospheric cure." He deserves great credit for his enthusiasm and energy. Afterward Dr. Lahmann, of "Weisser Hirsch" near Dresden, started a similar institution. It would seem that the success of this "cure" should no longer be disregarded by physicians, and it has become our duty to investigate its merits more closely. I have deemed it important to refer to this, as I consider this therapeutic agent the forerunner of our modern phototherapy, or treatment with the electric rays. Sunlight and electric light have the same effect on our system, and it has been proved by thousands of cases already treated that the beneficial result of treatment with electric light is due to the action of those rays which approximate most closely to the sunlight—namely, the blue and ultraviolet rays of the arc light.

Now, before entering into a discussion of the therapeutic value of the electric light, we have to answer the question, What are the physiological effects of light on the human organism, and especially upon its metabolism?

Very important investigations have been made in this direction as early as 1855 by Moleschott.[1] This author reached the following results: Frogs give off one-twelfth to one-quarter more CO_2 in the light than in the dark, *i.e.*, the temperature being equal or nearly so, and the units of body weight and time being the same. Further, the greater the intensity of the light, the greater the quantity of CO_2 given off, which is reduced to a minimum on foggy days.

Von Platen made experiments on rabbits, covering their eyes alternately with black and with transparent glasses. He proved that under the influence of the light the gaseous and watery exchanges were considerably increased. The oxygen consumption in the light and darkness was as 116 to 100; the elimination of CO_2 as 114 to 100. Later on Moleschott and Fubini demonstrated the fact that this influence upon the metabolism is present even after the eyes have been enucleated; that is, it is exerted also through the skin.

After the preliminary experiment of Reid, Scharling, and Marchand, it was proved by Pettenkofer and Voit that man gives off less CO_2 at night during sleep than in the daytime in absolute repose. They proved, therefore, that light is here of importance.

I omit the mass of all other researches regarding this particular question. Every one interested in it will find the literature in a work by Willibald Gebhardt,[2] entitled "The Healing-Power of Light," which every physician ought to read. I also refer to a dissertation by Franz Schoenenberger,[3] where a great deal of the literature can be found.

Having confined my investigation to diseases of the respiratory tract, it became necessary, in order to understand the finer mechanism of the rays of light, to study their effect upon the mucous membrane of this tract, and especially upon that of the bronchi, etc. In this respect the investigation of Dr. S. Bergel,[4] of Inowrazlaw, are of very great importance to us. Dr. Bergel, whom I have the pleasure of having known personally for a good many years, studied, entirely independent of the subject under discussion, some eight years ago the effect of light and darkness upon the movement of the ciliated corpuscles. He says that the peculiar behavior of the ciliated corpuscles toward light and darkness was of especial interest. He proceeded in the following manner: He put the microscope into a dark cabinet, which was placed upon the observation table. The cabinet was perfectly closed, with the exception of two openings. The one, when illuminated, was for the observer, but could be darkened by means of curtains when it was desired to shut the light off. Just opposite the microscope was another opening, which could be exposed to direct sunlight or closed, as desired.

Now, if a ciliated corpuscle in motion was placed under the microscope, and the latter darkened, it could be seen on inspection after a while that the motion of the corpuscle grew slower and slower, and finally ceased. The more rapid the vibration before the withdrawal of light, the longer the period of activity of the corpuscle in the darkness until it became motionless, and, *vice versa*, the slower and weaker the vibration of the cilia, the shorter the time up to the cessation of all motion.

When a corpuscle that had been kept in the dark, showing no motion whatever, was exposed to bright

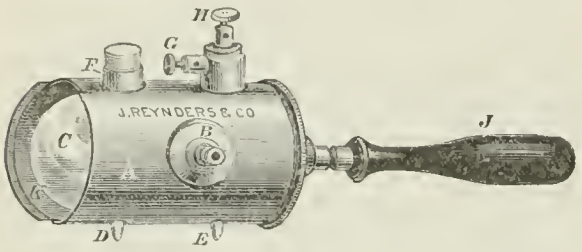
daylight again, the oscillation recommenced after a latent period, depending upon the duration of the exposure to darkness. The longer the corpuscle remained in the dark after it had become motionless, the longer it continued in a quiescent state until the resumption of oscillation. This could be repeated several times, but soon a sort of fatigue was noticed in the corpuscle. This showed itself also when the corpuscle was kept too long in the dark.

What do these important investigations of Bergel mean? Are they not in contradiction to our daily experience? The cessation of the movement in the dark seems to be opposed to the real conditions of life, as in the animal, or at least in the higher animal, the ciliated epithelia are in dark regions of the body, and, nowithstanding this, are in constant motion. I would mention here that in a series of experiments on ciliated corpuscles no cessation occurred, and these were the ones that moved quickest before they were put in the dark chamber. The light stimulus, it seems, shows its effect only on exhausted ciliated corpuscles,



which are no longer in full possession of their vitality. They still move on irritation, that is, when light is thrown on them; but when the stimulus ceases, that is, when they are brought into the dark, then they sooner or later cease to oscillate. Now, inasmuch as light acts as a stimulus upon the movement of the ciliated corpuscle, this is, according to Bergel, nothing but a proof that the ethereal vibrations of light have an influence upon the chemical processes within the corpuscle; they cause chemical changes, which are transformed into motion, or, in other words, into labor. Now we can understand the first experiment by Moleschott. Every action of the organism is accompanied by the chemical process known as oxidation. The more activity, the more oxidation; the more light was thrown upon the frogs, the more oxygen they consumed and the more CO_2 they gave off, and all this only through the greater activity of the ciliated bodies. In pathological conditions there is an accumulation of metabolic material which cannot be eliminated nor replaced by new nutritive elements; therefore the action stops, as the ciliated corpuscles are, so to speak, paralyzed.

In this connection I have to mention what is probably well known to all of you, that the actual labor done by these cilia in the human system is enormous. If, according to Justus Gaule, you excise in a frog just killed the mucous membrane of the pharynx and œsophagus, splitting open the latter and pinning the whole membrane on its edges on a piece of cork, and if you put small particles of soot or of cork or similar substances, dipped in a physiological salt solution, upon it, then you can see how these particles are carried away until they finally reach the stomach end of the œsophagus. Small as is the force of a single cilium, so enormous is the total effect of their immense number (Engelmann).

In the example just mentioned the current of the cilia is in the direction from the mouth to the stomach, as it is the function of the mucous membrane of the digestive tract to transport substances into the organism. The current is just the reverse on the mucous membrane of the respiratory tract, that is, from the bronchi to the nares. This is natural, as here there is different work to accomplish, namely, to carry the dust particles, etc., out of the organism. This work is initiated in the cells by the cilia nearest to the bronchi; then the others follow suit. Thus with "great intelligence" they sweep out during the night the dust that is inhaled during the daytime; and in the morning it is found deposited at the entrance, and with a little hawking, etc., it is easily removed.[1]

In tuberculous affections of the respiratory tract there is nearly always a concomitant catarrh present, with more or less mucus. Sometimes this is present in enormous quantities. That such a superabundant secretion should prevent entirely the oscillation of the cilia is very plausible. On the other hand, if this is present in a smaller degree, it will paralyze—as I understand it—temporarily the action of the cilia, and in such cases a stimulant like light will overcome this paralysis and the ciliary corpuscles will be able to resume their work. The metabolism of the cells will return to the normal, and coincidently not only the mucus, etc., will be removed from the bronchi, but, in my opinion, also the end product of the tubercle bacilli, and undoubtedly a great many of these bacilli as well. This would be the ideal cure of the disease. Alas, it is not always accomplished! but in many cases this beneficial effect in part is produced without doubt.

But has sunlight not a direct influence on the bacilli? We know now that it has, and I agree with Albert Abrams, of San Francisco, when he says:[2] "The value of sunshine in localities adapted to the treatment of consumption is greater than is generally believed. That this value is dependent in part upon the germicidal action of the solar rays in the atmosphere I am confident. I have made a number of experiments to test the influence of solar-heated atmosphere on the growth of tubercle bacilli in culture tubes. The results demonstrated that while such atmosphere was not destructive to the growth of tubercle bacilli, it nevertheless retarded their development." I have not hesitated to quote even such a conservative statement before you, although I am aware that the experiments of other authors have shown a still greater germicidal power of the rays of light. It naturally depends upon the time you use the sunlight for such purposes.

I myself was led to study the effects of light, and especially electric light, on the diseased tissues, in a very curious manner.

In 1889 I had the honor to demonstrate before the New York Academy of Medicine (section on laryngology) the transillumination of the larynx. One of the patients whose larynx I had frequently examined asked me one day whether I no longer employed "electricity," which always benefited her. As such patients who suffer with intense pain are usually not hysterical, I was constrained to give this matter my consideration. I applied the "electricity" by alternately placing the Voltolini light, modified by me, upon one or the other side of the larynx or upon the pomum Adami. As this lamp has in the mean time probably fallen into disuse, I will repeat here my former remarks:[3]

"The casing contains an Edison incandescent lamp and in front of it a ball filled with water, which is similar to the globe commonly used by shoemakers, and subserves the double purpose of, first, concentrating the light by acting as a biconvex lens, and, secondly, of protecting the exterior of the neck from too intense heat. I have taken the liberty of making a few minor

[1] See Gaule: "Physiologie der Nase" in Heymann's "Handbuch der Laryngologie," p. 161.

[2] Philadelphia Monthly Med. Journ., March, 1899, p. 175.

[3] Medicinische Monatsschrift, November, 1889

changes in this apparatus. In the first place I have increased the amount of light by using a higher-power lamp. It also appeared to me that in some patients with a large pomum Adami many of the rays of light were lost. For this reason I had the front part of the apparatus *A* (see figure) hollowed out and covered with rubber, so that it adapts itself better to the external contour of the neck. A handle *f*, which can be attached to a posterior or lateral surface *B*, seemed to me useful. Finally I had the globe more firmly attached, *D* and *E*, in order to protect it from breakage."

I then applied this lamp to one or both sides of the larynx or also in front, and usually allowed it to remain at the place of application until this became heated, ordinarily about five minutes. Several times I observed a formation of blebs after five to ten minutes.

At first I did not attribute any significance to this treatment, as I was at a loss for an explanation. Not until 1891, when I read the address made by Robert Koch before the International Congress in Berlin, was the matter clear to me. Koch referred to the influence of sunlight upon the tubercle bacilli—a view which was soon adopted by Mignano[1] and others. Later Minck, a pupil of Buchner, Santori, Marshall Ward, and a host of other investigators demonstrated the same influence of electric light upon bacteria.

If, therefore, sunlight as well as electric light accomplishes all that which has been demonstrated by most eminent investigators, there remained only for decision the question whether light actually penetrates the tissues of the larynx. This could not appear doubtful to me, since I had examined hundreds of patients by means of transillumination, and had been able to see distinctly the interior of the larynx. It seemed to me that if any portion of the body were adapted for testing the influence of electricity it must be the larynx.

My expectations were not entirely fulfilled, and I would ascribe this to the incompleteness of my apparatus, which permitted me to apply the electric light for only about five minutes to the diseased parts, after which it became too hot. Notwithstanding this I had some encouraging results, of which I would communicate the following:

Case I.—Mrs. R. H——, thirty years old, mother of four living children, pregnant. She has suffered four weeks with pain in the throat, especially on swallowing. On retiring she has a feeling as if "oil were boiling in her throat."

Status præsens, February 24, 1892: Phthisis incipiens of both lungs; mucous membrane of larynx very anæmic; slight ulcerations on the epiglottis and on the right ligamentum ary-epiglotticum. I administered creosote with tincture of gentian (equal parts) in increasing doses until she took seventy drops three times daily. Besides this I applied the electric light to both sides of the larynx.

March 10th: Up to this time the patient had appeared only once every week. The sensation of "boiling" in the throat was better after each application of the electric light, but the improvement lasted only for a short time. Later it was still troublesome enough to disturb her night's rest. From now on she calls every second day for treatment.

April 15th: The peculiar sensation described is still present, but much less marked; the pain is less.

April 27th: The sensation is still present at night; the pain is inconsiderable.

June 5th: The ulcers in the larynx have healed; she feels much more comfortable, has no sensation of "boiling" in the throat at night, no dysphagia, but some cough.

[1] Archiv für Hygiene, Bd. 25.

June 20th: She was ddelivered of a child, and feels comparatively well.

June 26th: She had a violent pulmonary hemorrhage, and died two days later in consequence.

Case II.—Mrs. M. S——, twenty-three years old, had one living child. She has a feeling of rawness in the chest, and complains of dysphagia.

Status præsens, November 7, 1893: Phthisis pulmonum (cavity of the size of the palm of the hand below the right clavicle); acute pharyngo-laryngitis; infiltration of both false vocal cords. Curettage refused.

November 17th: She was given codeine, creosote, and application of the electric light, the latter thrice weekly. Swallowing is much better, and she requests further application of the electric light.

November 24th: The condition of the larynx is the same, although the patient asserts that she is feeling better.

December 12th: The patient feels quite comfortable, and travels to Lakewood and then to Georgia, remaining away altogether ten weeks.

March 22, 1894: The patient had felt quite well up to a week ago, when she was seized with a violent cough, and also with a return of her former dysphagia. She was treated in the same manner as before.

May 10th: She had again improved so much that she was able to make a trip to the Adirondacks.

The patient had been under treatment of various laryngologists, and stated that nothing acted as well as the application of the electric light. I have heard nothing further from her, but she is said to have died in the Adirondacks.

Case III.—Miss L. B——, nineteen years old, singer, had a hemorrhage about one and a half years ago; she coughs a good deal, has pain on swallowing, and has been hoarse for four months.

Status præsens, November 25, 1895: Phthisis pulmonum, both apices being affected. Larynx: epiglottis somewhat infiltrated; deep ulcer on the left cord. Treatment: Creosote, codeine, antifebrin occasionally for the fever, and every second day application of the electric light to the left side of the larynx. Under this treatment she improved considerably, so that after three months, on February 28, 1896, the ulcer had healed and the patient was absolutely free from pain.

September 3, 1896, I again saw the patient, and found her in excellent health after a sojourn of six months in the country. The pulmonary affection was cured and no tubercle bacilli were found.

January 6, 1897: She coughs again for the past eight days and is troubled with slight dysphagia on the left side; superficial ulceration on the epiglottis (left side); acute laryngitis and diffuse bronchitis. The ulceration was obstinate, and she was not restored to complete health till after the lapse of fourteen weeks' (irregular) treatment.

I saw her again in December, 1897, and also in March, 1898, and was able to demonstrate a permanent cure.

I have since had my apparatus changed. In order to get only blue rays from the light I filled the little glass bottle with a very dilute solution of methylene blue instead of pure water. This gave me a nice blue color. As the metallic end of the lamp still became very hot by radiation, I attached a hard-rubber piece at the end of it, and in this way the apparatus remained cool, and the patients did not feel any annoyance from the heat. Still the water became so hot that once it drove out the cork, spilling the hot water over the bare chest of the frightened patient. After that occurred I modified this instrument again, and you see here the apparatus which I use now. Instead of the glass bulb filled with colored water I simply inserted a disc of colored gelatin or glass. In this way I have overcome

all difficulties. I can apply the electric light as long as I wish—as a rule for from thirty to sixty minutes—and I must say the results so far are very encouraging. These results demand consideration for a method of treatment which is so agreeable to the patient and so free from all injurious effects—phototherapy. We do not hesitate a moment to subject the patient to pain, if it can only be assumed that some relief is thereby afforded him. Have we not all of us caused severe pain by applying lactic acid and in using the curette, as well as other methods, all without avail? Therefore since the majority of my patients ask for the continuation of the treatment with the electric light because of the benefit which they ascribed to it, am I requesting too much in urging you to add this method to your therapeutic resources?

After having for years used the electric light for tuberculosis of the larynx, it was natural to give this a trial also in tuberculosis of the lungs. I have mentioned above that the electric arc light is the one which has produced, according to different German authors, the best results. I did not apply this in tuberculosis of the throat, as my results with the incandescent lamp were quite satisfactory. Besides, this lamp could be applied better to the larynx. It is different with the thorax; here we would have to place the patient in a box provided with a great many incandescent lamps, and the heat produced in such a cabinet would not be beneficial to tuberculous patients. I therefore resorted to the arc light, which I have applied in several cases. Encouraging as the results appear to be, I am not prepared to give you the histories of patients thus treated, nor can I present a definite opinion for one very important reason, viz., the instruments used up to the present time have not attained that state of perfection which they ought to have, and which I think can be reached easily. For the last twelve months I have been trying to have a more perfect apparatus made, but regret to say that I have not succeeded as yet. It is the hardest work to get a new electrical instrument made here in this city of Greater New York, although it is overflowing with electricity. Still I hope I shall have it finished in the near future, when I shall report my further experiences. But even now I am able to say that we have in the chemical rays of the electric light a healing-power which promises to be of the greatest value in the near future. The results so far achieved can no longer be ignored, and it has become our duty to investigate further these processes.

THE IMPORTANCE OF PRELIMINARY TREATMENT FOR INTRA-NASAL OPERATIONS.[1]

By CARL SEILER, M.D.,

SCRANTON, PA.

It is an axiom in general and special surgery that it is of great importance, whenever possible, to prepare the general condition of the patient as well as the parts to be operated upon before any surgical procedure is undertaken; to improve the general health, tone up the system, quiet the excited nerves by tonics and hygienic measures, good food and air as well as judicious rest alternating with mild exercise in the fresh air, aided by stimulants when indicated; in short, to bring about a condition of the system as nearly normal as possible, and to remove, as far as may be, any acute or subacute inflammation of the parts to be operated upon before the knife is resorted to.

In a large number of cases which come under the care of the general surgeon this preliminary treatment cannot be instituted for lack of time and opportunity, and as a result its importance with regard to the outcome of the operation is lost sight of; and it is but too often neglected in those cases in which both time and opportunity are present.

The surgeon in the majority of cases being obliged to rely upon the resisting-power of the system as it exists at the time, naturally falls into the error of neglecting to improve this "vis naturæ medicatrix" in those cases, few though they may be, which come under his notice, and in which opportunity and time are not lacking for such preliminary treatment. In intranasal surgery we have to deal with cases, on the contrary, but very few of which demand immediate operative interference (as in the case of traumatic injuries of the nasal bones or the impaction of foreign bodies in the nasal chambers), while the great majority allow of extended and often lengthy preliminary treatment, which, when undertaken intelligently, will amply repay all trouble and loss of time by the often apparently miraculously beneficial results of the operation.

In spite of the axiom, and in spite of the more or less emphatic warnings by almost all authors on the subject, not to operate before the preliminary treatment has been carried out, and not to operate while the nasal mucous membrane is in a state of acute or subacute inflammation (as during an attack of hay fever, for instance), this necessary precaution is not taken and the warning is not heeded by the majority of surgeons; and operations are performed without preliminary treatment, which thus prove annoying, painful, and even disastrous to the patient in their results.

I have found through extensive experience that in many cases this general and local treatment in itself is sufficient to ameliorate the direct as well as the reflex symptoms, notably insufficiency of accommodation of the eyes, to such an extent that an operation, which at first seemed inevitable, becomes unnecessary, and the patient is relieved without surgical interference.

Although this treatment has been freely discussed in detail in text-books and in current literature, yet the apparent neglect of it on the part of surgeons prompts me to refer to it again, and to give in outline only its salient features.

After a careful examination of the case has been made and we feel satisfied that many if not all the concomitant symptoms can be traced directly or indirectly to the presence of abnormal and pathological conditions within the nasal cavities, and that a removal of these conditions is necessary for a cure of the ailment, the preliminary treatment should be instituted.

First of all, the patient should be directed as regards diet and hygienic measures. Such tonics as may be indicated for the purpose of toning up the system and counteracting any of the effects of general dyscrasias, if such are present, should be given. Among the hygienic measures bathing of the neck and the upper portion of the chest and back with cold water or salt and water (one teaspoonful to one pint of water), morning and evening, followed by gentle drying of the skin with a soft Turkish towel, without friction, will be found very grateful and beneficial in those cases which are prone to acute congestion or inflammation of the mucous membrane of the upper air passages. It regulates the capillary circulation and hardens the skin of the neck and throat so as to withstand the frequent shocks of changes of temperature about the region of the neck, such as are caused by draughts of cold air striking the skin.

The local treatment of the nasal and naso-pharyngeal mucous membrane should begin with a thorough cleansing of the nasal cavities by the patient twice daily with a bland antiseptic solution of the proper

[1] Read before the Lackawanna Medical Society, Scranton, Pa., September 11, 1900.

density and temperature. As these various attributes are of the greatest importance in a proper nasal wash, so is also the method employed in washing out the nasal cavities by the patient himself, to both of which I have frequently called attention in the various editions of my book on diseases of the throat, and in various papers in current medical literature; but a more detailed description of both will nevertheless, I trust, not be out of place in this paper, particularly as physicians are so very apt to neglect thorough instruction of the patient as to how to use a nasal wash. It is not sufficient to tell the patient to sniff up "a little salt and water" for a nasal wash, without giving him the exact proportions of the salt to the water and the proper temperature (56 gr. [or more simple and quite accurate enough, an even teaspoonful] of table salt to one measured pint of water at blood heat).

In order to facilitate the making of the proper nasal wash, and to insure greater accuracy and efficiency of the solution, I devised several years ago a compressed tablet composed of salts and antiseptics, in such quantities and incorporated in such a manner that one pastil dissolved in four tablespoonfuls of warm water would give a solution possessing all the necessary properties mentioned for a proper nasal wash.

Unfortunately all the various and numerous manufacturers have imitated this tablet, which goes by the name of "Seiler's antiseptic pastil," without paying attention to the scientific principles in the manufacture which underly the efficiency of the preparation, so that to-day there is scarcely to be found in the market a preparation of Seilers' pastils but which is inefficient, and in many instances even injurious; hence I have been compelled to request the numerous manufacturers to withdraw my name from their preparation labels and lists, which request was granted by most of them.

Equally important, as already mentioned, is the method employed in cleansing and flushing, so to speak, the nasal cavities with the solution, by means of which a thorough cleansing of all their parts, and without undue pressure upon the column of liquid is obtained. It is therefore apparent that atomizers, syringes, nasal douches in their various forms, and even the sniffing from the hollow of the hand are all methods inadequate to the purpose in the hands of the patient, if they are not injurious, as is frequently the case with the nasal douches by forcing the mucus and the solution into the pharyngeal opening of the Eustachian tube when obstruction in either one of the nasal chambers exists.

What may properly be called the natural method, or, as some patients have graphically described it, "drinking through the nose," will be found to be at once easily taught and easily learned by the patient, and to be efficient without being harmful. It consists in placing two ounces of the blood-warm solution in a small tumbler or cup, placing the end of the nose within the rim of the tilted vessel until the liquid enters the nostrils, then closing the mouth, and by a moderate inspiratory effort drawing the solution into the nose and naso-pharynx, thus bringing it in contact with all parts of the nasal mucous membrane. The vessel should then be quickly removed from the nose and the liquid within the nasal cavities be blown out through both nostrils at once, and the process repeated until the liquid in the vessel is exhausted. If this cleansing process is faithfully carried out by the patient morning and evening, considerable advance toward the removal of congestion or inflammation will be observed. In the paroxysm of hay fever or acute coryza the greatest possible relief is experienced by the patient in a very short time, provided, however, that the solution is of the proper density and is unirritating.

This cleansing process should be continued by the patient, while local applications of mild astringents and alteratives to the mucous membrane of the anterior and posterior nasal cavities are made by the surgeon at intervals of a day or two. All the numerous astringents in solution with the atomizer and in powder form as snuff have been used with more or less success, but the iodine solution in glycerin (iod. met., gr. viii.; glycerin, fl ʒ ss.; potass. iodide, gr. xxiv.) has proved more universally useful than any other local remedy in my experience. It is best applied with a pledget of cotton on the end of a delicate armed applicator, which should be carried through the nostrils along the lower meatus into the naso-pharynx on both sides if it is possible to do so, which manipulation should be executed as gently as possible.

The hygroscopic property of the glycerin causes the iodine solution to rise and quickly to come in contact with the upper portions of the mucous membrane, so that it is not necessary to touch the more sensitive portions of the anterior nasal cavities with the applicator. In order to retain the iodine solution longer in contact with the nasal mucous membrane and prevent its being washed away by the often copious serous discharge following any local application, a triturate of bismuth subnitrate and gum acacia, equal parts, may be blown through the nostrils into the anterior nasal chambers. If necessary a direct local application to the naso-pharynx of the same solution may be made behind the soft palate with a curved applicator. Cocaine in any shape or strength of solution should never be used in the nasal cavities except as a local anæsthetic for minor intranasal operations, in which capacity it is invaluable. As its primary effect is a contraction of the capillaries of the nasal mucous membrane, its application, it is true, affords immediate but evanescent relief from the nasal obstruction due to turgescence of the blood-vessels and venous sinuses in the turbinated tissue; but after the cocaine has lost its effect a reaction takes place which calls for a fresh dose of the drug, and the patient for the sake of temporary relief, as in hay fever for instance, becomes addicted to the use of cocaine and cannot exist without a pledget of cotton saturated with cocaine solution in his nose. This habitual use of the drug has a relaxing effect upon the tissues, which become flaccid and pale; and any operation, no matter how trivial in its nature, undertaken when the nasal mucous membrane is in this condition and is kept cocainized afterward, is apt to be followed by extremely slow repair. This effect of the drug is, however, a purely local one, and the effects of cocaine upon the general system are but rarely observed in these cases of "nasal cocaine fiends," probably because absorption of the drug does not take place through the anterior portion of the nasal mucous membrane.

This preliminary treatment, as outlined here, should be kept up for several weeks, the local applications being made as stated, at frequent intervals, until a comparatively healthy appearing mucous membrane shows on examination. In those cases in which a bony or cartilaginous projection occludes one of the anterior nasal chambers while the other is the seat of atrophic changes in the turbinate tissue and in the mucous membrane, the atrophic side should be treated with stimulant astringents, such as zinci sulph. triturate diluted with sacch. lact. in varying proportions, or with nitrate of silver diluted with starch (gr. i. : gr. xxx.), insufflation, or finally with the cotton tampons in connection with the wash and the insufflations until a reaction from the atrophic condition has taken place, as indicated by the increased watery secretion found in the nasal cavity.

Very little and only that which is self-evident need be said of the treatment after an operation, except that the patient should be kept under observation for a con-

siderable time to insure a return to the normal condition of his nasal cavities, and to prevent any untoward little accidents, such as colds, from again interfering with normal nasal respiration.

A CONTRIBUTION TO THE DIAGNOSIS OF SUPPURATIVE APPENDICITIS.[1]

By A. ROBIN, M.D.,

PATHOLOGIST AND BACTERIOLOGIST TO THE DELAWARE STATE BOARD OF HEALTH, NEWARK, DEL.

"To operate or not to operate," that is the question, as perplexing as the one of existence was to Hamlet. There are just as many arguments for as against operation in cases of appendicitis. The surgeon who sees principally suppurative and far-advanced cases holds that only by a timely operation can a fatal issue be averted, while the general practitioner, on the other hand, who encounters largely cases of simple catarrhal appendicitis, contends that in many instances an operation is a useless exposure of the patient to a serious risk, and that such patients may and do get well without any surgical intervention. The author has examined an appendix removed from a physician who had had repeated attacks of appendicitis. On section, the lumen of the appendix was found entirely occluded by strong fibrous bands. Evidently the operation in this case was useless, inasmuch as nature was accomplishing a radical cure. On the other hand, we frequently read reports of cases in which life was saved by an operation, or could have been saved by timely surgical intervention.

Connected with the above contentions there is a minor one among the surgeons themselves. When shall we operate? During the intervals, immediately at the onset, or when suppuration is evident? It is clear that these differences of opinion will exist so long as we have no means of differentiating, at a sufficiently early date in the course of the disease, suppurative from catarrhal appendicitis, or are not able to foresee whether the catarrhal appendicitis will terminate in recovery or become suppurative.

In view of these difficulties, any aid we can get in the diagnosis of suppurative appendicitis should be welcomed by both the physician and the surgeon. Such an essential aid the author finds in a blood count, as the following case illustrates:

On October, 1899, the author was called in by Dr. Kollock of this town to see a colored girl, aged seventeen years, who was suffering from appendicitis. The attack was not very severe, the girl having been confined to bed only two days. The temperature at the time of our visit was 102° F. Constipation existed. On palpation a large oblong mass was felt in the right iliac region extending as far as the groin. This mass proved subsequently to be the distended ascending colon. It was tender on pressure. The abdomen was slightly rigid. Her general condition was fair. A blood count revealed 23,500 white blood cells per cubic millimetre. A diagnosis of suppurative appendicitis was made, and the girl was at once removed to the Wilmington City Hospital, and there operated on by Dr. Williamson, of Wilmington, Del. The appendix could not be found, but while searching for it the doctor broke some adhesion, and about two tablespoonfuls of pus welled out from beneath the distended colon. The attempts to find and remove the appendix were abandoned; the wound was flushed with sterile water and packed with gauze. The patient made a good recovery.

This case shows that suppuration was detected by means of a blood count when neither clinical symptoms nor external signs pointed to it. Had the girl been allowed to go on for another day or two, a large abscess would have formed, and even admitting that it would have been circumscribed by adhesions, the latter could have been easily broken, and if operated upon the danger of infection would have been much greater.

In order that the importance of a blood count may be better appreciated by the non-specialist, a few general remarks will not be amiss.

Our medical nomenclature in general is far from perfect, but when it comes to the nomenclature of blood it is below criticism—a veritable Babylonian mixture of terms indiscriminately applied. It is a very unfortunate thing to cover our ignorance by a high-sounding and alluring terminology, such as "idiopathic" disease, "alterative" action, "agglutinin," "vitality," etc. It were much better to follow the modest example of Roentgen and designate the unknown by *x*, thus calling at once the attention of everybody to the fact that the unknown quantity is still the unsolved part of the problem. How many *x*'s would we have in our medical science if this method were followed! As it is, we have "eosinophiles"—white cells possessing granules which take up the eosin stain, "lymphocytes," "polymorphonuclear neutrophiles," all terms applied to the leucocytes, a name erroneously employed as a synonym for white blood corpuscles. It is true that the word "leucocyte" means "white cell," but physiologists have restricted the term to the wandering cells which pass from the lymphatic spaces into the lymph channels and thence to the general circulation; they all possess amœboid movement, and it is to these cells that the term "phagocytes" has been applied by Metchnikoff on account of their property of imbibing and digesting bacteria. The term "leucocytes" therefore, as applied by the physiologists, would mean the lymphatic cells outside but not within the blood-vessels. These lymph-corpuscles or leucocytes entering the circulation from the thoracic duct become white blood corpuscles. In infectious diseases the lymph-corpuscles, and not the white blood cells, are increased (with few exceptions). This may *a priori* be expected, knowing that the lymphatic system is stimulated to activity in any infectious disease. This increase in the number of leucocytes brings about indirectly an increase in the number of white blood corpuscles, and indeed it is by the increase of the latter that we judge of the increase of the former. The term "leucocytosis," therefore, may be used, providing its physiological meaning is kept in view. But here again we confront an error in nomenclature. "Leucocytosis" is used whenever we want to designate an increase in the number of leucocytes; the word itself, however, means "morbid state of white cells" (from the Greek, λευκός, "white," κύτος, "cell," and suffix—osis, "morbid state." This "morbid state" exists whether the number of leucocytes is above or below normal, and the terms hyper, "above," and hypo, "below," prefixed to leucocytosis is the more proper terminology.

The importance of leucocytosis asserted itself since the discovery by Metchnikoff of the property possessed by the leucocytes of imbibing bacteria. This property, however, is not specific to leucocytes nor to bacteria; it is the sole means by which many unicellular organisms, such as the amœbæ, nourish themselves. The particles imbibed are granules, bacteria, etc. The imbibition of bacteria by the leucocytes, therefore, is not a defensive act, as one would be led to believe from the fantastic picture painted by the adherents of the "phagocytosis" theory. While swallowing the deadly morsel, the leucocyte is not thrilled by any altruistic or patriotic emotion. The bacterium is simply within its reach, the stimulus is sufficient to cause expansion and contraction of the protoplasm of the leucocyte, and the morsel is devoured regardless of consequences. A

[1] Read before the Cecil County Medical Society, Md.

granule of carmine would suffer the same fate. To this phenomenon of attraction the term "chemiotaxis" is applied. It is not necessary at this place to enter more deeply into the theory of "phagocytosis" as explaining immunity. Suffice it to say that the theory, universally accepted prior to 1893, is no longer tenable. It does not explain the immunity acquired against toxins, such as toxins of diphtheria, in which case the bacilli themselves are altogether excluded. Recently, Metchnikoff tried to stretch his theory by ascribing to the phagocytes the property of secreting the immunizing substances. These, however, are speculations which do not interest us at present. Whatever rôle the leucocytes play in establishing immunity, it is a well-established fact that their increase or decrease is of considerable diagnostic significance. The normal proportion of white blood cells is 1 to 300 or 1 to 700 red (5,000–10,000 per cubic millimetre), somewhat higher in women and considerably higher in infants (about 20,000 per cubic millimetre). Physiologically it is increased after a meal, during pregnancy and parturition, after exercise, and as shown by Winternitz' after a cold bath (this explains the salutary effects of the latter in typhoid fever). Pathological hyperleucocytosis takes place in the following diseases: Hemorrhage, scarlet fever, diphtheria, tonsillitis, syphilis (secondary), erysipelas, pneumonia, malignant endocarditis, puerperal and other septicæmias (in the case of puerperal septicæmia not of aid in diagnosis), trichinosis, glanders, acute multiple neuritis, acute articular rheumatism, septic and cerebrospinal meningitis, infection of the gall bladder, acute pancreatitis, some acute cases of cystitis, gonorrhœa, all kinds of abscess formation, gangrenous inflammations, and various forms of toxæmia. Some drugs such as pilocarpine, antipyrin, etc., produce hyperleucocytosis, while atropine and other anidrotics have the opposite effect. Infection with cultures of the colon bacillus, as has been demonstrated experimentally by Bohland,[2] produces hyperleucocytosis, and some cases of cystitis in which hyperleucocytosis is found may be thus explained. Hypoleucocytosis, or diminution in the number of leucocytes, takes place in fasting and malnutrition, and in some infectious diseases, such as typhoid fever, malaria, influenza, measles, mumps, and tuberculosis, except in advanced stages.

It is thus seen that a white blood count will often swing the pendulum in the direction of the diagnosis of one disease or another. Especially is this true in cases of suppuration complicating an infectious or inflammatory disease. Thus a sudden hyperleucocytosis in the course of typhoid fever will point to a complication, and if accompanied by sudden onset of pain in the abdomen will be a sufficient justification for an exploratory incision, as is the practice in the Johns Hopkins Hospital. A hyperleucocytosis will at once differentiate a suppurative appendicitis from simple colic, typhoid fever, ovarian neuralgia, impaction of fæces, and floating kidney. Developed during the course of a catarrhal appendicitis it will point to suppuration with as much precision as any of the diagnostic signs in our possession. The case above described certainly lends support to this assertion. The girl was not very sick, only two to three days in bed and comparatively comfortable, and yet the presence of pus was as patent to our minds as though demonstrated by an exploratory operation. Cabot tabulates seventy-two cases of appendicitis in which blood counts were made. The following show the relation of suppuration and hyperleucocytosis:

No. 1. 52,000 leucocytes—pus found on operation.
No. 2. 19,000 " —pocket of pus found.
No. 15. 22,300 leucocytes—abdomen full of pus.
No. 17. 21,900 " —pus; cæcal abscess.
No. 18. 47,700 " —second operation; pus.
No. 18. 30,300 " —third operation; pus.
No. 23. 20,000 " —operation, pus.
No. 28. 19,000 " —purulent peritonitis.
No. 31. 17,500 " —pint of pus.
No. 34. 16,200 " —abscess cavity.
No. 40. 32,800 " —large amount of pus.
No. 50. 17,000 " —pus.
No. 54. July 6. 11,800 leucocytes, slight tenderness, no resistance or dulness.
No. 54. July 7, 19,000 leucocytes up to, resistance and tenderness; operation, pus.

The last case shows how by means of a blood count pus can be detected within twenty-four hours and a fatal case be thus converted into a very favorable one. What other means have we of diagnosing suppurative appendicitis? Unfortunately none. What we are able to diagnose is a purulent peritonitis, but then we have done our patient very little good, even if we are able to fill out a correct death certificate. We may also occasionally detect a walled-off abscess, if it points externally, but in how many cases does the abscess take such a favorable turn? It appears rational, therefore, that a frequent blood count in cases of appendicitis is almost an imperative necessity. I say frequent, because in some fulminant cases the advent of fatal toxæmia may be so rapid that no increase of leucocytes is present. This is fully in accord with the experiments on animals performed by Havet,[1] who has shown that whenever the dose of staphylococci injected was very large, the ability of the organism to produce leucocytes was proportionally abolished, and instead of the usual hyper- a hypoleucocytosis took place. Similar observations were made by Everard, Demoor, Schultz, and others. Cabot reports four cases of appendicitis with general purulent peritonitis in which no hyperleucocytosis was found. When, however, examinations are made frequently such mistakes would in the majority of cases be avoided, for we could always detect the hyperleucocytosis before the organism would become sufficiently depressed to fail to react. With all these facts before us, we can hardly fail to appreciate the important rôle a blood count plays in the diagnosis of suppurative appendicitis.

INTESTINAL OBSTRUCTION COMPLICATING APPENDICITIS, WITH THE REPORT OF A CASE.

By THOMAS M. PAUL, M.D.,
ASSISTANT SURGEON STATE HOSPITAL, HAZLETON, PA.

Asepsis has so reduced the mortality of laparotomy that conservative surgeons perform this operation in grave cases for purposes of diagnosis as well as treatment. Still further, asepsis has stimulated the progressive operator to devise means for mechanically treating conditions which would have been considered beyond the surgeon's reach in days when bacteria were unknown. That many lives have been saved by operation in obscure abdominal conditions, and that what has been supposed, even by eminent surgeons, to be an appendicitis with abscess has turned out to be a pyosalpinx, is evidence in contradiction to the teaching of a few years ago. An interesting case is recorded by A. F. Jonas, in which an enterolith was mistaken for appendicitis, and after cœliotomy for malignant disease.[1]

What is true of the technique of laparotomy in general is equally true of progress in the treatment of in-

testinal obstruction in particular. Unless the occlusion of the bowel is due to fecal impaction, which is generally relieved by purgatives and enemas, or to advanced carcinoma, it is not only justifiable but absolutely necessary to operate. It is as important to relieve an invisible obstruction by mechanical means as to cut the constriction in a case of strangulated hernia. The earlier the operation is performed in these cases the better the general and local condition of the patient will be, and in consequence the better the prospect for recovery. Richardson well expresses this when he says: "Six cases . . . have occurred in the writer's experience; three died and three recovered. In the three fatal cases the operation was performed as a last resort, the patients' condition being practically hopeless."[2] In opposition to these ideas an edition of a well-known text-book appeared as recently as 1893, in which all sorts of palliative measures were advocated, its author stating that operative interference is to be resorted to only as a final procedure.

In an extensive research into the literature of intestinal obstruction I have been able to collect only six cases[3] in which it was due to the appendix itself, although surgical text-books seem to consider it a not unusual cause. As for ileus due to inflammatory adhesions, which adhesions in turn are due to appendicitis, I have read of only two instances.[4] I consider it of interest therefore to report the following case:

B. B——, aged sixteen years. Family history negative. In June, 1899, he had an attack of acute appendicitis lasting two weeks. A second attack began July 31, 1900. This attack also lasted about two weeks, at the end of which time the patient got out of bed. The second day after getting up he ate plentifully of green apples. The last of the apples was eaten about 3 or 4 P.M., and about 10:30 P.M. he was seized with violent pain in the abdomen and vomited a considerable quantity of the apples. During the night he had a good free movement of what his mother described as the undigested apples. From this time until the time of admission to the hospital, a period of three days, the patient had no intestinal evacuation, but vomited frequently.

Examination on admission, August 19, 1900: The patient was generally well nourished; he was very much depressed and answered questions only after they had been repeated; the pulse was 110, wiry, and irregular; the respiration slow and feeble; the temperature 97° F. The abdomen was generally distended, but more so above than below the umbilicus; there was no visible peristalsis. Pain and tenderness were general, although more pronounced in the neighborhood of the appendix. The liver dulness was replaced by tympany, which extended well over on both flanks and down to the pubis. No borborygmi or gurgling could be heard.

As high enemas and purgatives had been tried by the family physician, further delay was considerd dangerous and the patient was immediately prepared for cœliotomy.

Operation, August 19, 1900, 3 P.M., performed by Dr. Lathrop, assisted by Dr. Dyson and myself. Ether was the anæsthetic used. The usual incision was made for the removal of the appendix, which was found embedded in a mass of adhesions. These were separated with difficulty and the appendix was ligated and amputated. The cæcum was collapsed, although several coils of small intestine, which had been drawn out in the search for the appendix, were distended almost to the bursting-point. A systematic search was then made, beginning at the cæcal end of the small intestine; after about four feet had been drawn through the abdominal wound, an adhesion encircling and completely occluding the gut was discovered. The intestine above this constriction was so distended that it was drawn well out of the abdomen and a small incision made in it, letting out a large quantity of fluid fecal matter. The offending adhesion was readily broken through by the finger. The intestinal wound was sutured, the peritoneal cavity thoroughly flushed with decinormal salt solution, and the abdominal wound closed with gauze drainage.

Toward the end of the operation the patient suffered from severe shock, despite the fact that the coils of intestine withdrawn from the abdomen were surrounded with hot wet gauze, and that hypodermics of strychnine were administered and hot-water bottles were kept applied to the body and extremities. After being placed in bed, the boy vomited a large quantity of fecal liquid, which further added to his depressed condition. He sank rapidly; the pulse became almost impalpable, the respiration shallow and rapid, and the temperature subnormal; and he became semi-conscious. Two quarts of hot decinormal salt solution were then gradually forced into the median basilic vein by means of a Collins' transfusion apparatus. Under this treatment the patient rapidly improved; he could talk coherently, his pulse became regular and full, his respirations were normal, and his temperature rose to 99.5° F. The following morning his bowels moved naturally. The gauze drainage was removed on the second day after the operation, and the wound healed rapidly. The remainder of his convalescence was uneventful. The patient was able to be up September 11th, and left the hospital September 16, 1900, perfectly well.

This case appeals to me as being unusually interesting for the following reasons:

1. It is exceptional to be able to ascribe ileus to appendicitis with the degree of certainty that could be done in this instance before the abdomen was opened.
2. It emphasizes the importance of early operation.
3. It demonstrates the value of the intravenous injection of decinormal salt solution in cases of shock, particularly when the solution is gradually forced in, the transfusion apparatus under these circumstances acting as an artificial heart.

Vertigo of Ménierè.—After a general description of the disease Urban Pritchard gives the history of a case occurring in a woman aged fifty-four years with left otorrhœa since childhood. In her fifty-second year she was admitted to hospital with large masto-squamous abscesses, foul otorrhœa, and inability to walk without assistance in consequence of vertigo. Operation was performed, but the bridge and outer wall of the attic were not removed. Two years later she again presented herself with practically the same symptoms. A complete mastoid operation was then done, but in the removal of the petrous bone the semicircular canals were in part destroyed, and the back of the vestibule was opened. Clear fluid escaped. Later an epithelial grafting operation was done with complete relief to deafness and giddiness.—*Journal of Laryngology*, September, 1900.

Recurring Parotitis in a Healthy Child, Persisting for Six Years.—F. C. Ewing reports the case of his own son, eight years old, who ever since his second

year has been subject to recurring attacks of swelling and inflammation of the parotid glands, apparently idiopathic. The swelling has always manifested itself suddenly, as a rule developing to its fullest extent during the night, with little or no constitutional symptoms. With one exception it has been unilateral. These attacks have occurred at irregular intervals of a few months to a year, becoming notably less frequent as the child has grown older. They are attended with pain on pressure and mastication, but it is never intensely acute. There has been no attendant enlargement of the lymphatics, nor the slightest hypertrophy after subsidence of the acute symptoms. These swellings have always disappeared without treatment within three days, generally decreasing somewhat in twenty-four hours. Fever has been absent. The subject is a vigorous boy, and considerable of an athlete for his years. He has never been specially subject to colds, nor shown the catarrhal diathesis. His family history was good; physical history was confined to great-aunts.—*St. Louis Medical Review*, September 15, 1900.

Life Insurance and Cardiac Disease.—F. G. Finley says that the cases which an insurance company is safest in accepting are those of mitral regurgitation and aortic direct murmurs in which secondary changes in the heart are slight or absent. Cardiac symptoms, particularly dyspnœa on exertion, should be excluded by the personal observation of the examiner, and as far as possible all cases should be excluded in which the lesion is likely to be progressive. Recurring rheumatic attacks exert a most unfavorable influence owing to further attacks of endocarditis or pericarditis. A station in life not involving manual labor, and early adult life, at which period arterial sclerosis is unlikely to be present, are further elements which must be weighed in the acceptance of such cases. Careful habits and good general health are also important in estimating these risks.—*The Medical Examiner and Practitioner*, September, 1900.

Sarcoma of the Naso-Pharynx Cured by Injections of Formalin.—The patient of J. A. Thompson was a man aged fifty years, who had had several hemorrhages from the nose and mouth ascertained to be due to a tumor in the naso-pharynx. His general condition was very poor. Examination revealed a mass attached to the posterior wall of the naso-pharynx, proven by the microscope to be a round-celled sarcoma. The patient's general condition contraindicated operation, and it was decided to inject one-half-per-cent. solutions of formalin into the growth. Twenty-five minims were used at each injection, the latter being made twice a week at the physician's office, while the patient used at home a cleansing spray. The injections seemed to remove the blood supply from the part of the growth injected, which was then removed by forceps. In this way the entire mass was completely eradicated. No recurrence was noted fourteen months after the treatment was begun. Finally the case was dismissed. No recurrence had been noted three months later.—*The Laryngoscope*, September, 1900.

Is Strychnine Neutralized by the Living Animal Tissues?—S. J. Meltzer and G. Langmann have repeated and elaborated the experiments of Czyhlarz and Donath with a view of testing the accuracy of their statements regarding the possibility of preventing the toxic action of strychnine by ligating for several hours the extremity into which it is injected, the assumption being that the poison is modified and made harmless by its contact with the tissues. As another example of such action Czyhlarz and Donath referred to the satisfactory results in treating snake bites by ligature, but in testing this in rabbits and guinea-pigs with the venom of Crotalus horridus it was found that death was delayed but not prevented by tying off the affected limb. In a similar way in experimenting with strychnine injections in rabbits, guinea-pigs, and frogs it was found that the toxic action was delayed and diminished somewhat, but that it was much more probable that this effect was due to the impaired absorptive power due to the congestion, œdema, etc., secondary to the ligation, rather than to any neutralizing power unfolded in the tissues.—*Centralblatt für innere Medicin*, September 15, 1900.

Disinfection of the Hands by Means of Essences.—Eugenio Calvello draws the following conclusions from a series of experiments: 1. That washing with soap and water and alcohol does not make the hands aseptic, although it does diminish the number of germs to a great extent. 2. That the methods of Fürbringer and Ahlfeld do not result in complete disinfection. 3. That seven to eight per cent. solutions of essence of cinnamon, eleven per cent. of essence of thyme, and seventeen per cent. of essence of geranium act precisely as do solutions of bichloride used according to Fürbringer's method, and should be given the preference in modern surgery, because they do not cause the alterations that bichloride does. 4. Nine-per-cent. solutions of essence of cinnamon, eleven and twelve per cent. of essence of thyme, and eighteen per cent. of essence of geranium assure complete disinfection of the hands. 5. The essence of patchouli has no antiseptic powers.—*Giornale Internazionale delle Scienze Mediche*, September 15, 1900.

The Continued Use of the Antiseptic and Eliminative Treatment of Typhoid Fever without Any Deaths.—Virgil Hubbard defines his modified Woodbridge treatment of typhoid fever as follows: Generally the patient is first given a capsule containing calomel, gr. ss; guaiacol carbonate, grs. ii.; podophyllin, gr. $\frac{1}{20}$ to $\frac{1}{40}$, every two hours for twenty-four to forty-eight hours, depending on the condition of the bowels. This is continued till four or five intestinal evacuations for two successive days have been secured, when the calomel is stopped and gr. ss. of menthol is added to the guaiacol and podophyllin. If after stopping the calomel there is any tendency for the bowels to become inactive, a small dose of salts is given in the morning. There should be two or three evacuations daily. If after four or five days of treatment the temperature remains high, or rises after having remained stationary, the calomel is again resorted to for a few hours. The guaiacol and menthol are continued throughout the course of the disease. Besides, the writer often administers decinormal salt solution per rectum. The collected results of the writer's cases, together with those of other men, treated in this manner give a mortality of less than two per cent., the writer having had no deaths.—*Georgia Journal of Medicine and Surgery*, September, 1900.

Renal Asthma.—S. W. MacIlwaine says that while renal asthma is familiar enough we do not pay sufficient attention to the pre-albuminuric stage when one might hope for some definite results from treatment. All cases of asthma coming on after middle life ought to be looked on with suspicion. Most of these cases are doubtless due to toxæmias of more or less obscure origin. Some light is probably thrown on their true nature by comparing them with the very rapidly fatal cases of so-called Bright's disease that are met with in elderly people as a result, or rather a part, of influenza. Here the consequences of a toxæmia of easily recognized origin fall directly on the kidneys. There is, in some cases, never more than a very small amount of albumin, the history is terribly short, and

the symptoms are almost purely uræmic: there is no time for the development of dropsy and other more tardy symptoms of kidney breakdown.—*Medical Press and Circular*, September 29, 1900.

The Etiology of Acute Lobar Pneumonia.—In a statistical presentation of certain studies in the bacteriological field W. T. Howard, Jr., found in one hundred and seventy-four consecutive autopsies fourteen cases of primary and fifty-three of secondary pneumonia. The pneumococcus was found in all cases of primary croupous pneumonia, in pure culture in eight, with the streptococcus pyogenes in one, and with the bacillus mucosus capsulatus in one. In the thirteen cases of secondary croupous pneumonia the pneumococcus occurred alone in six cases, the streptococcus pyogenes alone in two cases, streptococcus pyogenes and staphylococcus aureus in two cases, streptococcus pyogenes and bacillus mucosus capsulatus in one case, streptococcus pyogenes and bacillus coli in one case, and bacillus mucosus capsulatus in one case in pure culture. Thus the pneumococcus occurred alone in nearly fifty per cent. of the secondary croupous pneumonias, while the streptococcus was concerned in the etiology of the same number, but occurred alone in only two cases. In all thirteen cases the pneumonic process was clearly secondary and often accidental.—*Cleveland Journal of Medicine*, September, 1900.

Pneumatocele of the Auditory Canal.—A case of this nature is reported by M. Lannois. His patient was a man of twenty-four who played in the orchestra of a theatre. Six days before while playing he had been attacked with a sudden deafness of the left ear. Examination showed in the corresponding auditory canal, one centimetre from the entrance, a large pearly-looking swelling slightly ulcerated at one point. A probe was passed by the mass which was easily compressible. On incision with a paracentesis needle, the swelling entirely disappeared, and the patient heard with about the usual facility. The accident happened several times, and finally Lannois curetted the portion of the bony wall over which the swelling seemed to form. This led to a complete cessation of the annoying repetitions of the accident.—*Revue Hebdomadaire de Laryngologie*, August 18, 1900.

Rapidly Progressive Anæmia.—H. W. Syers reports a rapidly fatal case in a woman of thirty-four years. The etiology is altogether obscure. The whole duration of the illness was exactly two months, and in this short period the patient passed from a condition of apparently vigorous health through rapid phases of increasing weakness, until death ended the scene. No remission, no arrest of symptoms occurred at any period of the malady, which was one swift descent to the fatal end. The author says that if we are ever to arrive at a real knowledge of the pathology of cases such as the one here recorded, it can only be by the methodical investigation of the blood in every case of disease. When this knowledge is acquired, we may perhaps be able to explain the occurrence of such peculiarities as apparent pericardial friction sounds, and the tendency to hemorrhages, cutaneous and other, which so strongly characterize acute blood changes.—*Treatment*, September, 1900.

Hysterical Ankle Clonus.—Angel Money says that the great characteristic of pure hysterical paraplegia is the remarkable proneness of the phenomenon to vary from hour to hour in harmony with emotional and nervous excitement. One day the phenomenon may be elicited with the greatest ease and may persist for many minutes; the next day only a few feeble jerks may be obtained. All degrees of intensity and duration between these two extremes may be observed. Some clinical investigators regard an ankle clonus lasting for five seconds as a sure sign of organic implication of the pyramidal tracts. The author thinks this absolutely inaccurate. His opinion is, that if an ankle clonus of unvarying intensity, obtained by passive dorsal flexion, lasts thirty seconds, and can be got at any hour of the day and night over a period of seven days, the presence of organic disease of the pyramidal tracts may be diagnosed with certainty. To prove the presence of organic disease, the clonus must be easily obtained, must be strong, and must last thirty seconds. Moreover, it must be obtained at every attempt over a period of at least a week..—*The Australasian Medical Gazette*, August 20, 1900.

Researches into the Toxic Properties of Maize Corn Infected by the "Penicillium Glaucum."—Enrico Ferrati in his experiments on dogs and rats finds that corn infected with hyphomycetes is poisonous, causing general weakness, rigidity of the trunk and hind legs, dysphagia, diarrhœa with bloody stools, convulsions, and death. Schizomycetes undoubtedly may produce poisonous substances in corn, but the author believes the penicillium glaucum to be the chief agent as a rule. The hyphomycetes develop under conditions in which the schizomycetes cannot do so, and moreover, the latter so affect the corn as to cause an odor which prevents its use as food.—*Il Policlinico*, September 1, 1900.

Prophylaxis of Surgical Shock.—W. M. Perkins states that the importance of perfecting the prophylaxis of shock is now attracting more general attention. Among the widely different causes to which shock has been attributed are molecular vibration, cerebral anæmia, cardiac failure, passive abdominal hyperæmia, general vasomotor paresis, and reflex inhibition. Briefly, shock seems to consist essentially of a central nerve depression due to the exhaustion induced by long-continued or violent stimulation, and manifesting itself in symptoms referable to three main causes, viz.: (1) a vasomotor paralysis; (2) a respiratory paralysis; (3) a cardiac paralysis. Crile has especially insisted upon the difference between collapse and shock. Inhibition is probably the most potent factor in collapse, while in shock exhaustion plays the more important part. Surgical shock may be greatly diminished by careful pre-operative prophylaxis. All fatigue, both mental and physical, should be avoided. When practicable, the final purgative should be given at least twenty-four hours prior to operation. The patient should remain in bed twelve hours previous to operation. Restful and abundant sleep should be taken. Nutrition should be promoted by several days of well-planned wholesome feeding. Gentle flushing of the kidneys is another factor, as are baths and friction of the skin. Loose clothing and an abundant supply of fresh air must be urged during the last few days. The question of anæsthesia will demand careful consideration. Ether is preferable to chloroform as a general anæsthetic in the absence of any contra-indication. A hypodermic of morphine sulphate $\frac{1}{4}$ gr., with atropine sulphate $\frac{1}{150}$ to $\frac{1}{60}$ gr., to which may be added strychnine sulphate $\frac{1}{30}$ gr.. is well given about twenty minutes before starting the anæsthetic. After the anæsthetic has been given there may occur conditions demanding the administration of ammonia, amyl nitrite, or saline infusion; inversion of the patient may be indicated in threatened respiratory failure. Speed is an essential to successful operation. The proper temperature of the room, the patient, and the solution should never be forgotten.—*New Orleans Medical and Surgical Journal*, October, 1900.

New York, October 27, 1900.

THE DIAGNOSIS AND TREATMENT OF ANÆMIA.

THE scientific mind must be ever an open one, without prejudice or prepossession, alive to every new increment of knowledge, yet not too ready to surrender the old, in order that on the one hand secure ground shall not be given up and that on the other theories and hypotheses that have outlived their usefulness may be replaced by new and better ones, and their application and practice yield larger and more successful results. The time happily is passing when a sharp demarcation can be made between the scientific and the practical, as it has been amply demonstrated that no scientific observation is without practical potentiality, although this relation may not at the time be evident. Inasmuch as language is employed to express ideas, it can be understood how erroneous conceptions may be perpetuated through a faulty nomenclature and progress be thus intercepted. In this way some confusion has arisen from the use of such qualifying terms as idiopathic, essential, primary, etc., and for purposes of clearness it were perhaps well if their employment were abandoned. Disease is at best a most complicated process, of complex etiology, and it is not surprising that at times all of the causative factors and their mode of operation do not fall within the range of observation; but for this reason it must not be assumed that they do not exist or are beyond the limits of recognition. The force of some of the foregoing considerations is illustrated in a communication by Senator (*Berliner klinische Wochenschrift*, 1900, No. 30, p. 653) dealing with the recognition and the treatment of the several varieties of anæmia. The designation anæmia, he points out, is employed when the condition of blood-depravity is, if not the only, at least the most prominent symptom. It may develop without obvious or ascertainable cause, as well as result from most obtrusive influences. It has, however, been found that a sharp discrimination between the two sets of cases cannot be made, inasmuch as, once established, the disease may persist, in spite of removal of its exciting agency; and it seems probable that, after all, the influences acting injuriously on the blood are of extrinsic origin.

As tuberculosis may be early attended with anæmia, and carcinoma of the abdominal organs or of the bones may give rise to the same condition and be difficult of detection, these should always be thought of when other causative factors are not evident. In any event, macroscopic and microscopic examination of the stools, especially for ova and blood, should never be omitted. In all cases of profound anæmia, further, microscopic examination of the blood should be undertaken for the detection of changes in the corpuscular elements and of the presence of parasites, as for instance, the plasmodium of malaria, filaria sanguinis hominis, distoma hæmatobium. Finally, a study should be made of the motor and chemical functions of the stomach, as deficiency in these may give rise to anæmia. A proper appreciation of the relations between the two conditions may be difficult when anæmia is associated with the presence of some disease that may give rise to it, such as carcinoma of the stomach or carcinoma or other malignant disease of bone or the bone-marrow. The latter are sometimes characterized by pronounced albumosuria.

Chlorosis has been attributed to auto-infection from the gastro-intestinal tract, and also from the ovaries. Upon this condition iron acts almost like a specific, but when gastric derangement exists hydrochloric acid should be administered. Sometimes the waters from alkaline-chlorine springs are serviceable, followed by steel waters or saline iron waters. Of pharmaceutical preparations of iron, combinations with organic acids (lactic, citric, acetic) are to be preferred, although tincture of the chloride and pills containing the sulphate are useful. In cases in which iron fails to be of service, arsenic may be given alone or together with iron or with quinine. In recent years venesection and sweating have been in some instances employed in the treatment of anæmia. The latter should be induced by means of baths with water, sand, or air. It is possible that the good effects attributed to bleeding are due in part to the associated sweating.

Among the distinctive features of pernicious anæmia is the presence of myeloblasts and of large, motile erythrocytes, the motility of the latter being especially characteristic. In addition, there occur poikilocytosis, the presence of normoblasts, of basophile granules in the erythrocytes, glycogenic degeneration (the presence of iodophile material) in the leucocytes, and a disproportionately high percentage of hæmoglobin. The waxy yellow color of the skin is peculiar, and the subcutaneous fat may be preserved. Sternal tenderness is rarely wanting, while retinal hemorrhage is common and symptoms of spinal disease may be present. Although complete recovery cannot be looked for in cases of pernicious anæmia, marked improvement often follows the administration of arsenic, together with quinine in large doses, in conjunction with appropriate hygienic and dietetic measures. Preparations of bone-marrow and inhalations of oxygen are also worthy of trial.

The anæmia that develops after sudden ascent to a high elevation is to be attributed to the attenuation of the oxygen of the air, and consequently of the blood, and hence is really an anoxyhæmia. The number of red blood corpuscles undergoes increase, in which the hæmoglobin fails to take corresponding part, so that a disproportion between the two results. This may gradually disappear in time, but its results are best

averted by change of residence to a lower level, with recumbency in the horizontal position, and the administration of stimulants. Inhalations of oxygen or of compressed air might also be useful.

AMPUTATION AT THE KNEE JOINT.

There are several methods of performing amputation at or near the knee joint which are well thought of and usually mentioned in text-books, but their several advantages and disadvantages do not always receive the attention to which they are perhaps entitled. In the region of the knee, as elsewhere in the body, amputations are done for injury or disease. In the case of injury, the general principle, that as little tissue should be sacrificed as is consistent with the formation of a serviceable stump, holds as elsewhere in the body, so that under such circumstances we are often not able to carry out a set operation when we are dealing with an injury which requires amputation.

The region of the knee presents some anatomical characteristics which from the operative point of view make it different in many respects from other parts of the body. The ends of the bones forming the joint are comparatively very large, and the skin and subcutaneous tissue are both comparatively and absolutely thin, and in addition the largest joint in the body is to be dealt with. There are in general two ways in which amputations in the immediate region of the knee joint are done—first, directly through the joint, and, second, through the lower end of the femur with the bone section at or somewhere below a point just above the condyles. The latter method, while sacrificing a little more tissue than the method of cutting through the joint, has some points in its favor. In operating through the joint, the so-called Stephen Smith method is almost always chosen, sometimes with modifications, but always involving the formation of a long, sleeve-like skin flap disposed so that at the end of favorable healing the cicatrix is placed posteriorly in and above the intercondyloid notch. The patella may or may not be left in place, and it will often be found advisable to leave the semilunar cartilages also, though there is some danger of their necrosis. This operation has given many good stumps, but there are several objections to it. If the patient has atheromatous arteries there is serious danger of more or less extensive sloughing of the long flaps, and a collection of very little blood between the articular surfaces of the femur and the flaps, even in those with healthy arteries, causes much more serious interference with healing than the same state of affairs when two surfaces of vascular soft parts are apposed. Union between the articular surfaces and the subcutaneous tissue of the flap is never so prompt as to be called truly *per primam:* in fact, it is probable that true granulation must begin on the cartilaginous surfaces before union can occur. When the patella is left in place and healing is prompt the resulting stump is very good. The chief drawback to this operation is the employment of the very long skin flaps, which on slight provocation show evidences of more or less serious interference with blood supply, which may result in necrosis and the necessity of reamputation. The operation named after Gritti, and its modifications, eliminate some of these objections by the removal of the lower end of the femur and the posterior surface of the patella, so that, when the resulting surfaces are placed in apposition, we are able to use a shorter skin flap and one with a better blood supply, without any important decrease in the length of the stump. The flaps are both actually and proportionately shorter than in the first operation, because the removal of part of the large end of the femur enables us to get good covering for the bone with much less tissue than we should otherwise need. From the Gritti operation the resulting stump is excellent, and the dread of sacrificing a little more tissue should not deter us from doing the operation, when we are enabled thus to secure greater safety from the dangers of tension or imperfect blood supply in the skin.

VENTILATION AT THE ACADEMY.

The season's work is about to open in all its activity at the Academy of Medicine, with every prospect of success and interest we hope, but there is one point of which we should like to speak, though it seems almost an act of temerity to do so in connection with a temple partially devoted to the worship of Hygeia. The ventilation in the academy building, in the main hall, in the library, and in the section rooms is nothing less than abominable. After a meeting has been in session an hour, especially in the sections, the air becomes so foul that it is impossible to take a great amount of interest in the proceedings, and many become somnolent or seek relief in flight. Opening of windows gives some relief, but this is usually objected to by those who, from exigencies of space or for other reasons, sit near those openings. This matter is one which it ought not to be difficult to correct, and it seems almost an absurd anomaly that it should exist, but that it does exist will be made evident to any one who will sit through a moderately crowded section meeting, or attend one of the meetings in the main hall.

News of the Week.

A "Bunco" Game on Doctors.—A correspondent writes: "I desire your assistance in the apprehension of the persons who are working a very sharp and dangerous 'bunco' game, and in protecting other members of the profession from the misfortune which I have suffered. The game is worked through the pretended sale of goods from the Omaha Exposition, and is begun by a circular offering most attractive articles at absurdly low prices. The fraud is consummated by the sale of dress-goods for about twice their value, with an agreement to make them into suits for a nominal price as an advertisement for the tailor, who, however, never appears. If any one of your readers who sees this, and has reached the circular stage of the

game, will communicate with me through you, I shall be happy to join with him in a scheme to capture these rascals and bring them to a merited punishment."

The Will of the Late Dr. Alfred Stillé bequeaths to the College of Physicians of Philadelphia all such of his medical books as are not contained in the library of the college; a full set of his own works; his manuscript indexes of pathology and therapeutics in nine volumes; his copy by Leslie of Sir Joshua Reynolds' portrait of John Hunter; his copy text and plates of Audubon's "Quadrupeds"; all of the medical works of which he was either author or editor, viz., "General Pathology," "Andral on the Blood," "Therapeutics and Materia Medica," four editions, each in two volumes; the "National Dispensatory," four editions; "Cerebro-Spinal Meningitis," "Cholera," the (pirated) edition or report of his University lectures; Wharton and Stillé's "Medical Jurisprudence," three editions; and whatever other medical works still remain in his library, first and second editions, and all the current medical journals possessed by him at the time of his death, as well as a number of dictionaries. To the Stillé Medical Society of the University of Pennsylvania are bequeathed all of the photographs of the society in his profession.

The State Sanatorium for Consumptives.—Considerable opposition has developed against the selection of the Big Lake Clear site for this institution. The site was selected by the hospital trustees, comprising Howard Townsend, of New York City, Dr. J. H. Pryor, of Buffalo, Frank E. Kendall, of Saranac, Dr. Willis G. MacDonald, of Albany, and Walter E. Jennings, of New York City. The law requires the establishment of the site in the Adirondacks, and that the selection of such a site by the trustees must be approved by the State forest preserve board and the State board of health. These two boards held a meeting a few days ago at Albany to listen to arguments why the selection of the Lake Clear site should not be approved by them. There were many persons at the hearing from Clinton county who want the sanatorium located in Dannemora. As the two boards can only approve a site selected by the trustees, a resolution was adopted requesting the trustees to make a further investigation of the Dannemora site and compare its climatic and other advantages with those of Big Lake Clear. Many persons who own camps in the Adirondacks insisted that the hospital should not be built on Lake Clear, as they held it would be contrary to public policy to locate such a charity in a region thronged with pleasure seekers, where the inmates of the hospital must either be subjected to unnecessary and undesirable restraint or permitted to range over the country, and come in frequent contact on the roads and lakes, if not also in the hotels and camps, with crowds of summer visitors. Dr. Ransom, who has been the prison physician at Clinton prison, Dannemora, for the past twelve years, made the principal argument in favor of the Dannemora site. He said that this is on the dryest slope of the Adirondack range, and its climatic conditions are superior to those of Lake Clear. The prison consumptives are all sent to Dannemora, and the percentage of consumptive deaths there is less than in the Lake Clear and Saranac regions.

Koch on Malaria.—According to the newspapers Dr. Robert Koch, who was recently in Hong Kong on his way to Europe from Batavia, announces that he has conquered malaria, having discovered means of preventing the spread of the disease in malarious districts and even of stamping it out completely. He also says he has prepared a remedy which is both curative and prophylactic. The latter will probably be put upon the market as soon as the eminent professor can make satisfactory arrangements with some German chemical house of good financial standing. He also declares that he has found a certain method of ridding a country of the malarial mosquito. Whether or not this is merely the prelude to another fiasco of the nature of Koch's tuberculin announcement time will show. In the mean while, concerning his scientific honesty, the New York *Times* says: "As might have been expected from the previous course of Dr. Robert Koch, there is not a word in the announcement of his successful investigation of the cause and cure of malaria to indicate that he is not alone in this field of study, or to hint that he has simply been following a line carefully marked out long ago by other scientists and since developed by them with an industry and ability at least equal to his own. This is not to say that the Berlin bacteriologist is either industrious or able; he is both to a high degree; but his reputation—out of Germany, at any rate—is that of a man not less businesslike than scientific, and he has been charged before now with a somewhat unprofessional tendency to monopolize glory and profits in a way not quite compatible with delicacy of sentiment. His recent labors in China have apparently brought nearer to the point of actual demonstration the theory that malaria and mosquitos are closely related, but that is not his theory, except by adoption, and he might well say more than he does about the English surgeon stationed in India who originated it, and about the men of the same and other nationalities who have done so much to lend it credibility."

Philadelphia Pediatric Society.—At a stated meeting held October 9th, Dr. W. O. Xander read a report of two cases of infectious nephritis in children. The patients were cousins residing in the same house, who became ill consecutively, following some disorder attended with swelling of the neck, and which might have been glandular fever, mumps, or scarlet fever. Other cases of mumps had been observed in the neighborhood. Dr. Thompson S. Westcott described a method for the differential modification of the proteids of milk in percentage mixtures. Drs. Hamill and MacLachlin presented a case of congenital syphilis with rapidly destructive lesion. In addition to a vascular nævus on the right side of the face and also one in the right scapular region, the patient, an infant three weeks old, presented ulceration of the right half of the upper lip and at the inner canthus of

the right eye, together with lesions of the palate on the right side. From the distribution of the lesions, it was pointed out, the case was suggestive of a trophoneurosis rather than of syphilis. A report was presented by the milk commission of the society, giving the results of examinations of dairies and milk for producers who have signed contracts with the commission, with an announcement of those whose milk has come up to the required standards. Two dealers have complied with all of the conditions, and others give evidence of striving to attain them. The requirements refer to the proportion of cream and the chemical constitution, and also to the relative bacterial purity of the milk. Dr. Maurice Ostheimer reported a case of fatal intestinal hemorrhage of unknown origin in an infant aged five months. Careful examination after death failed to disclose any cause for the hemorrhage which occurred in the marantic child, and in whose body no sign of tuberculosis or syphilis was found. It was suggested that the case might be an anomalous one of hæmophilia. Dr. John H. Jopson reported a case of stricture of the pharynx following intubation. The patient was a boy from whom the tube could not be removed until after the forty-first day. Symptoms of laryngeal obstruction developed several months subsequently, necessitating tracheotomy, but death resulted from pneumonia complicating an intercurrent attack of measles. Post-mortem examination disclosed cicatricial stricture of the larynx.

The Smoke Nuisance.—The following remarks of Sir William Richmond, quoted in *The Lancet*, are of interest to New Yorkers, who are now threatened with the evil of bituminous coal smoke: "It is cheaper to consume smoke than to allow it to pass into the atmosphere. Smoke is wasted fuel. At a comparatively small cost all factories, electric-lighting stations, etc., can be provided with smoke-consuming apparatus. This being the case the public has only to demand a clear atmosphere—anyhow as far as the smoke from factories, steamers, and railway engines is concerned—and they will get it. The vestries and the L. C. C. do not enforce the law against smoke partly on account of apathy, but chiefly because in those bodies there are many smoke-makers, or friends of such." We trust the apparent immunity enjoyed by certain offenders in this city—notably several large hotels—is not due to apathy or the other thing of the health authorities.

Philadelphia County Medical Society. — At a stated meeting held October 10th, Dr. William Campbell Posey read a paper entitled "The Successful Removal of Cataracts in Insane Subjects, with Recovery of Mind Attending the Restoration of Sight." Dr. Lambert Ott presented a paper entitled "Clinical Laws of Immunity to Disease," citing numerous instances illustrating apparent antagonisms between, and susceptibilities induced by, various infectious diseases. Dr. F. Savary Pearce made a communication entitled "Heart Disease or Epilepsy," in which he pointed out the difficulty sometimes encountered in reaching a decision as to the nature of perversion or loss of consciousness. Dr. Ernest Laplace exhibited a new aseptic ether and chloroform inhaler, consisting of a hemiovoidal receptacle with a crucial opening and containing sterile gauze held in place by a strip of wire gauze of similar form. The advantages claimed for the apparatus are its readiness of sterilization and its simplicity of manipulation and preparation.

Petition for a Municipal Hospital.—The City Council of Camden, N. J., having failed to comply with the request of the board of health for the establishment of a municipal hospital, the medical profession of that city has presented a petition renewing the request and pointing out the urgent need of such an institution.

The Health of the Navy in the Philippines.—In his annual report to the secretary of the navy, Surgeon-General Van Reypen says that, considering the climatic conditions and the necessary exposure, the health of the squadron on the Philippine station has been remarkably good. It has been and still is the practice to send officers and men who are suffering from debilitating climatic conditions to the naval hospital at Yokohama, where, as a rule, they soon recover and return to their stations for duty.

Philadelphia Hospital.—In accordance with resolutions adopted by the bureau of charities, the clinical teaching at the Philadelphia Hospital is to be amplified. In addition to a continuation of the regular lectures on Wednesdays and Saturdays, ward classes not exceeding ten are to be encouraged; surgical and gynæcological operations are to be opened to students under proper restrictions; clinical instruction in insanity is to be made a new feature, and instruction in the specialties and in pathology is to be permitted. Dr. Joseph McFarland and Dr. Simon Flexner have been elected additional pathologists.

The Medical Society of Virginia.—The thirty-first annual meeting of this society was held at Charlottesville on Tuesday, Wednesday, and Thursday, October 23d, 24th, and 25th. The president was Dr. Hugh T. Nelson, of Charlottesville, the recording secretary Dr. Landon B. Edwards, of Richmond, and the corresponding secretary Dr. J. F. Winn, of Richmond. The chairman of the committee of arrangements was Dr. J. Hamilton Browning, of Charlottesville. The subject for general discussion at the Wednesday morning session was malaria, the leader of the discussion being Dr. H. Stuart MacLean, of Richmond.

Typhoid Fever in a Brooklyn School.—The occurrence of many cases of typhoid fever among the inmates of the Boys' Disciplinary School in Brooklyn, has brought to light an insanitary condition that would have been thought impossible under an efficient board of health. Ten cases of the disease were reported on Monday, and the inspector of contagious diseases found everything most favorable for an epidemic outbreak. The boys' dormitory was found to be without adequate ventilation, the beds were crowded so closely together that there was barely room to walk between them, and in place of a ceiling, which was recently

destroyed by fire, there was only a rough open planking. Directly behind the school was an open ditch, said to communicate with the sewer. This was in a frightful condition and during the day the sun would beat down upon the filth, flies feast upon it and from it fly into the kitchen where the food for the boys is prepared. The back yard was literally honeycombed with old cesspools that were not properly cleaned.

Dr. William B. Savage, of East Islip, N. Y., was appointed consulting surgeon to the Manhattan State Hospital at Central Islip, at a meeting of the Board of Managers held October 10th.

Smallpox in the Klondike.—A steamer recently arrived at Vancouver from Skagway brings the report that smallpox is raging along the Klondike creeks, many of them being quarantined. There were twenty-two cases in Dawson on September 15th.

Cholera in Japan.—A despatch received in St. Petersburg, on October 23d, from Vladivostock says cholera is increasing to such an extent in Japan that steamships from there have been quarantined. A number of deaths have occurred on board of steamships from Nagasaki.

The Shah of Persia is said, in a recent cable despatch, to have consulted over a dozen physicians in the different countries he has visited in Europe. He is believed to be suffering from kidney trouble, but declares that no two of the many doctors who examined him were in accord as to his actual condition.

Typhoid Fever is very prevalent in New York at the present time, and several well-known members of the medical profession are ill or have recently recovered from the disease. Among the former we regret to say is Dr. Reginald H. Sayre, and among the latter we rejoice to say is Dr. Emil Mayer.

Typhoid Fever at Newport.—The epidemic of typhoid fever at Newport, R. I., is subsiding, few new cases having been reported since the middle of the month. In three weeks there were forty-five known cases with six deaths. Examination of the wells and cisterns in the city has shown several of a suspicious character, one in particular being found to contain typhoid bacilli in abundance. One result of the epidemic is the getting up of a petition addressed to the city council, praying that the board of health be restored and the committee on sanitation, which consists of city-council members, be abolished.

The New York Obstetrical Society.—At the annual meeting of this society, held October 9th, the following officers were elected: *President*, Dr. H. J. Boldt; *First Vice-President*, Dr. Ralph Waldo: *Second Vice-President*, Dr. H. N. Vineberg; *Recording Secretary*, Dr. G. L. Brodhead; *Assistant Recording Secretary*, Dr. G. G. Ward, Jr.; *Corresponding Secretary*, Dr. E. E. Tull; *Treasurer*, Dr. J. Lee Morrill; *Pathologist*, Dr. W. S. Stone.

The University of Dallas has recently received its charter from the State of Texas and the first board of directors has been elected. The incorporators are empowered to teach law, medicine, the arts and sciences, and to confer all professional and academic degrees usually granted by universities. At present only the school of medicine will be inaugurated. The faculty consists of the following physicians: Drs. J. E. Gilcreest, of Gainesville; V. B. Armstrong, of Dallas; B. E. Hadra (president Texas Medical Association), of Waco; S. E. Milliken, of Dallas; Joe Becton, of Greenville; L. Ashton, of Dallas; C. M. Rosser, of Dallas; A. F. Beddo, of Dallas; J. B. Titterington, of Dallas, dean of the faculty.

The Late Prof. Lewis A. Sayre.—At a recent meeting of the Faculty of the University and Bellevue Hospital Medical College, the following minute was entered on the records:

The members of the Faculty realize with deep regret their great loss in the death of their late colleague, Prof. Lewis A. Sayre, M.D. His long and honorable professional career has shed lustre on the calling of his choice and on the medical school to which, at its birth, he plighted his earnest support, and which he sustained with loyal vigor until his death.

While bowing in humble submission to the will of Him "who doeth all things well," we extend to the members of his family our earnest assurance of sympathy in this their great affliction.

HERMANN M. BIGGS, *Secretary.*

Dress Reform in Texas.—Dr. C. A. Lindsley, secretary of the Connecticut State Board of Health, in his monthly report, issued October 16th, says: "The authorities of El Paso, in Texas, are a judicious and considerate body. They object to the practice, so much in use by the gentler sex, of wiping the sidewalks with their trailing dresses and carrying accumulated microbes, mud, spittle, and other filth into habitations and occupied places, to be dried and shaken off in the air and so to render respiration therein disgusting and dangerous. They have proceeded to the extent of their authority by prohibiting the admission of teachers within the public schools except in 'short skirts.' Their example ought to be imitated throughout the United States." Dr. Lindsley's commendation of this reform is needed in Connecticut, for in two or three towns in that State the school commissioners have forbidden teachers to wear short skirts and even dismissed two who persisted in dressing hygienically.

The Roentgen Society of the United States.—The first regular meeting of this society, the object of which is, as its name implies, "the advancement of the knowledge of practical *x*-ray work and allied arts and sciences," will be held at the Academy of Medicine in this city on December 13 and 14, 1900. The following are the officers of the society: *President*, Dr. Heber Robarts, St. Louis, Mo.; *First Vice-President*, Dr. J. P. Girdwood, Montreal, Canada; *Second Vice-President*, Dr. H. P. Bender, Brooklyn, N. Y.; *Secretary and Treasurer*, Dr. J. Rudis-Jicinsky, Cedar Rapids, Iowa; *Assistant Secretary*, Dr. Carl Beck, 37 E. 31st Street, New York. The secretaries of all scientific, medical, surgical, dental, electro-therapeutical, and all auxiliary societies, wishing to be represented,

are requested to send in the names of the delegates on or before the meeting in December. All those wishing to become members or to read a paper before the society may communicate with the secretary.

The Society of Russian Surgeons was recently established in Moscow, membership being open to all practitioners in Russia upon the payment of 8 rubles yearly or 100 rubles at one time. The organizing secretary is Professor Diakanoff, of Moscow.

Marriage of the Unfit.—At the meeting of the Tri-State Medical Society of Tennessee, Alabama, and Georgia, recently held in Chattanooga, Tenn., steps were taken to obtain medical legislation in these three States for the purpose of regulating or prohibiting the marriage of habitual criminals, persons afflicted with incurable diseases, drunkards, and victims of harmful drugs.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending October 20, 1900. October 15th.—Medical Inspector E. C. Derr detached from the navy yard, Portsmouth, N. H., on reporting of relief, and ordered home to wait orders; Surgeon B. F. Stephenson ordered to the navy yard, Portsmouth, N. H., October 25th. October 16th.—Assistant Surgeon H. E. Odell ordered to the Asiatic station modified; to take passage on the *Solace*. October 17th.—F. B. Stephenson commissioned medical inspector from May 31, 1900; Assistant Surgeon H. A. Dunn detached from the *Dorothea* and ordered to the *Frolic*.

The New Jersey Board of Dental Examiners.—Charges have been brought by several members of this board against one of their fellow-members of incompetency as an examiner. It was alleged that he was slow in getting up papers for examination, that he sometimes forgot papers, and that he changed the marks made by another examiner on a certain student's papers, with the remark: "I generally mark higher than you do, so I will mark 20 instead of 18." The accused member stated, at the hearing of the charges before Governor Voorhees a few days ago, that with two exceptions he had always turned in his papers promptly. He said that he had never confined himself closely to the text books, but gave credit if a practical knowledge of the subject was shown even if it did not have the exact text-book answer.

The Late Dr. John M. Brown.—At a meeting of the medical board of the Metropolitan Dispensary and Hospital, the following resolution was passed:

"Inasmuch as by the death of Dr. John M. Brown the Metropolitan Dispensary and Hospital has sustained a loss which is poignantly felt and with difficulty retrieved, and since, individually, we miss the rugged honesty, the incorruptible friendship which was constantly evidenced to us who knew him intimately, be it

"*Resolved*, That this feeble expression of our esteem for his character and our appreciation of our loss be spread on the minutes, and a copy of this resolution be sent to his family and to the medical press."

Obituary Notes.—Dr. William R. Larkin, of this city, died on October 15th after a brief illness. He was born in this city forty-two years ago, and was graduated from Bellevue Hospital Medical College in 1883. He spent two years at St. Vincent's Hospital, where he was house surgeon, and in 1885 began practice in Harlem. At one time he was on the staff of the J. Hood Wright Hospital, and at the time of his death was a member of the Harlem Medical Association.

Dr. Henry Moreton died at his home, a dingy little drug store in this city, on October 20th at the age of ninety-three years. He was born in England, but came to this country with his brother in 1828 and opened a drug store. His brother was a physician and he himself studied medicine later, being graduated from the College of Physicians and Surgeons in 1845. He always retained his shop and never removed from the neighborhood in which he first settled. He abandoned practice a number of years ago.

Dr. James F. Mahoney died at his home in this city, after a lingering illness, on October 15th, at the age of thirty-five years. He was a graduate of Bellevue Hospital Medical College in 1882. He practised for about four years only, and was then appointed an inspector in the customs service at this port.

Dr. Harold E. Hobby, a dentist of Mount Vernon, N. Y., died on October 20th, at the age of twenty-two years, from accidental asphyxiation by illuminating-gas.

Dr. Philip Roth died suddenly at his home in Newark, N. J., from cardiac trouble, on October 21st. He was born in Newark in 1864 and was graduated from the College of Physicians and Surgeons in 1884.

Sir Henry Wentworth Dyke Acland, of Oxford, England, died on October 16th at the age of eighty-five years. He was honorary physician to the Prince of Wales, whom he accompanied on his visit to this country. He was born in 1815, and was educated at Harrow and Oxford. He was Regius Professor of Medicine, Oxford, 1857–94, and member of the Royal Sanitary Commission, 1870–72. Among his publications is a "Memoir on the Visitation of Cholera in Oxford in 1854." He had been Radcliffe Librarian at the University of Oxford since 1851. In 1879 he revisited New York as the guest of General McClellan.

Capt. Benj. Brooke, late a surgeon in the United States army, died at Radnor, Pa., on October 18th at the age of thirty-four years. He was graduated from the medical department of the University of Pennsylvania in 1889 and served subsequently as a resident physician in the Philadelphia Hospital.

Dr. William F. Reilly died at Carlisle, Pa., on October 19th, at the age of forty-two years. He was graduated from the medical department of the University of Pennsylvania in 1875, and was for ten years assistant surgeon in the Eighth Regiment, N. G. P.

Dr. William H. Sturgeon, the oldest physician in Fayette County, Pa., died at Uniontown on October 15th, at the age of seventy-two years. He was graduated from Jefferson Medical College in 1849.

Dr. David Pellman Boyer died at Philadelphia on October 14th, at the age of seventy-six years.

Progress of Medical Science.

Philadelphia Medical Journal, October 20, 1900.

The Germ of Yellow Fever.—Charles Smart speaks of the work of several bacteriologists with reference to this subject and quotes a communication from Dr. Reed under date of July 24, 1900, in which he states, in relation to the present outbreak of yellow fever at Pinar del Rio, Cuba: "Our laboratories are now in good working order. We have been able to study carefully seven cases since our arrival. Of these, one resulted in recovery (a severe case) and six were fatal. Neither during life nor after death have we been able to isolate bacillus icteroides; but our sixth autopsy, which occurred day before yesterday, cannot be definitely reported upon as yet." Agramonte believes that Sanarelli's bacillus icteroides is no more concerned in the production of yellow fever than are the common colon bacilli which are frequently found in the blood and viscera of individuals suffering or dead from yellow fever. Lutz believes that those observers who report that they have found the bacillus icteroides in all cases and that they can make the diagnosis by the agglutinating action of the blood, are the victims of gross errors of observation. Lutz believes that this bacillus cannot be found in more than half the cases of yellow fever by known methods of research. Agramonte reports that he has isolated Sanarelli's bacillus from three cadavers in which death was not due to yellow fever.

Report of a Case of Tetanus with Recovery.—Andrew H. Whitridge reports this case of a young colored man who entered the hospital complaining of a burned foot. The interesting points in the case are that the first symptom of tetanus manifested itself on the thirteenth day, and nine injections of tetanus antitoxin serum, 10 c.c. each, were made, but were followed apparently by no improvement. Morphine, gr. ⅙, was then given hypodermically every four hours, the dose being increased in a few days to gr. ¼, showing most happy results in abating the spasms and irritability of the muscles. The patient made a perfect recovery.

The Present State of Our Knowledge Concerning the Cause, Nature, and Treatment of Asthma.—The conclusions of W. A. Wells are as follows: (1) Asthma has so many points of resemblance with migraine, angina pectoris, and epilepsy that the suspicion may reasonably be entertained that they all have a similar pathology. (2) Of the theories which have been advanced to explain the pathogenesis of the asthmatic paroxysm, no one of them so well harmonizes all the facts as the vasomotor theory; and this only when we admit that the disturbance is essentially that of arterial contraction, rather than dilatation. (3) There is always present in asthma a morbid constitutional state, affecting especially the sympathetic nervous system and giving rise to a certain nutritional aberration, whose most salient feature is the increase of uric acid and the urates. (4) Asthma occurs as a reflex neurosis from diseases of different organs, but especially often from those directly supplied by branches of the vagus nerve. The nasal trouble, which is the most frequent reflex cause, is not necessarily an obstruction and may be very inconspicuous and difficult to detect. (5) Nearly all cases of asthma show evidences of a pronounced psychic element, as in the curious variety of exciting causes of the attack, in the capriciousness of its course and behavior, and its dependence upon emotional states, suggestion, etc. (6) In the treatment of the paroxysm of asthma, a strict individualization needs to be observed. The best remedies are those which overcome arterial spasm, such as morphine, nitroglycerin, atropine, and chloral hydrate. (7) Treatment in the intervals of the attacks must be directed, in the first place, to the removal of the cause, and secondly, to the institution of sound hygienic and prophylactic measures in relation to the mind, diet, air, exercise, etc. (8) Medicinal treatment is addressed to improving the constitutional state, for which the best remedies are piperazin, iodide of potassium and the other iodides, the alkalies, and general tonic treatment.

Electrolysis in the Treatment of Stricture of the Lacrymal Passages.—L. L. Mial gives a review of the history of this special application of electrolysis and speaks enthusiastically of results which he has obtained in a series of cases in which probing extending over a long period had failed to afford relief. Each of the patients exhibited a mucopurulent discharge which rapidly ceased, especially as to purulency, after two or three applications of the current through a Bowman probe at intervals of a week. Advantages are: rapid result, absence of pain, no bleeding, and antiseptic action. Current strength should not exceed three milliampères. The positive pole is a flat sponge applied to the nape of the neck. Sittings should not exceed two minutes. Even this length of time may cause considerable hyperæmia with itching and pain lasting a day or two. Mial recommends in addition the washing out of the canal, after withdrawal of the probe, with a four-per-cent. solution of protargol.

Bullous Enlargement of the Middle Turbinate Bone (Concha Bullosa).—Two cases are reported by J. Payson Clark, who mentions two additional cases which have come under his own observation. Twenty other cases have been recorded. Four-fifths of all were in women. Seventeen were in persons under twenty. Clark regards the condition as of developmental origin. In twelve of the twenty-four cases the cells contained air only, five were complicated by the presence of polypi, one contained a yellow viscous fluid, and in seven the nature of the contents was not mentioned. Symptoms are headache, nasal obstruction, sense of intranasal pressure, and possibly disturbances of smell, discharge (from complicating sinus disease or of the cell cavity), photophobia, and overflow of tears. Removal with the wire snare or forceps is the only rational treatment.

The Diagnosis of Pulmonary Tuberculosis.—Robert H. Babcock states that this may be easy or difficult, depending on the stage of the disease and the nature of the pathological conditions. If the temperature shows a constant elevation ranging between 99.5 and 100.5 F., it is in a suspected case strongly suggestive of tuberculous infection. As a rule the pulse is accelerated and to a rate out of proportion to the temperature. Respiration may or may not be increased. In incipient cases there is usually no dyspnœa. Loss of weight is suspicious and is an invariable accompaniment. Cough is frequently symptomatic of this disease, but not invariably so. Sputum, when present, exhibits nothing characteristic unless it shows bacilli. As to physical signs, one of the earliest is lessened expansion of one apex. Another is atrophy of the scapulo-thoracic muscles on the affected side, also drooping of the shoulders. Palpation does not furnish very reliable or positive information except as corroborative of that obtained by other means. Percussion is greatly relied on, but is not always so trustworthy as is auscultation. Auscultation is valuable for the early recognition of pulmonary tuberculosis, but requires considerable skill. Mensuration of the chest is an accessory method. There is a wide diversity of opinion concerning the use of tuberculin for diagnostic purposes. The *x*-ray is now affording valuable information in regard to the condition of the lungs. Agglutination of the blood, after the Widal method, is too recent and not sufficiently proved to require more than a passing mention. All of these diagnostic points are particularly applicable to the disease in its incipient stages. As to the advanced stages, the symptom complex alone is sufficient, but examination of the chest should always be made. It may be accepted as a general rule that dulness and broncho-vesicular or bronchial breathing and râles at the apex indicate pulmonary tuberculosis. Signs of excavation corroborate the diagnosis.

State Provision for the Treatment of the Consumptive Poor.—Benjamin Lee declares that the only ground on which state charities can be justified is that of self protection. From the standpoint of political economy and true statesmanship, the maintenance of hospitals simply for the relief of suffering and healing of diseases is a gross misuse of public funds. In the case of infectious disease, the dangers arising from its extension justify the expenditure of large amounts of money. It is the acceptance of the view that tuberculosis is communicable that makes it possible to urge the state to contribute to the care of the consumptive poor as such. The knowledge both of the curability and the preventability of consumption should be spread abroad.

In Germany, France, Great Britain, Sweden, Belgium, Holland, Spain, and Roumania much has been accomplished. An international congress of tuberculosis has been held. The New York State board of health has adopted resolutions urging the early construction of a State sanatorium for consumptives in the Adirondacks at a cost of not less than $200,000. The legislature of that State has already passed a bill authorizing large cities to establish hospitals for sufferers from tuberculosis. Massachusetts has aleady in operation an institution of this kind at Rutland, which cost $150,000. Other States are taking up the movement. The United States government has established a sanatorium at Fort Bayard, N. M., for the care of its soldiers affected with this disease. The day is coming when this disease, which kills four and a half times as many as smallpox, scarlet fever, typhoid fever, and diphtheria combined, will be properly taken care of.

Climate for Tuberculosis.—Norman Bridge states that although climate is important, it is only one element in the proper management of this disease. To increase the resisting-power of the body is the great requirement. Practically there are no occupations that are wholly hygienic—especially no indoor work. The needs of the tuberculous patient apart from special me lication include: (1) Rest from work; (2) change of work and cares; (3) attention to the digestion and the feeding and nutrition of the body; (4) long hours of sleep; (5) outdoor life, sunshine, and fresh air; (6) a change of surroundings for novelty and pleasure; (7) a change of climate, to a better one if possible, but a change anyway. The chief value of any climate for tuberculosis depends on the time spent out of doors and the amount of pure air breathed all night—at the same time laying aside depression and hardship. Sunlight is valuable. Altitude helps some cases, especially the incipient ones. Dryness of air is an important element. Homesickness wholly counteracts any good effect of climate in many cases. With other conditions as favorable as possible, a good climate is an influence that will often tip the balance in favor of recovery. Nothing more than this should be asked of any climatic resource.

Municipal Regulation of the Spitting Habit.—Elmer B. Borland has been during the past year in communication with the boards or bureaus of health of tweuty-two principal cities of the United States. An analysis of the information received from them on this subject may be formulated as follows: Special laws have been enacted in one-half of these cities, and about one-fourth are regulating partly or wholly under their general nuisance acts. These ordinances empower bureaus of health to abate or prohibit anything of an unsanitary character; indiscriminate spitting is included. In the past five years, New York and Brooklyn, Newark, Columbus, Cleveland, San Francisco, Pittsburg, Washington, D. C., Rochester, New Orleans, Louisville, and Baltimore have enacted special laws. The boards of health of Philadelphia and Boston are doing good work under their general nuisance acts. Public opinion is being rapidly educated and the work is well begun.

Overcrowding and Tuberculosis.—S. A. Knopf declares that lack of air and light, intemperance, and underfeeding help to create in the body the best soil for the invasion, growth, and development of the tubercle bacilli. These conditions predominate in many of the city tenements. He then speaks of the great danger attending the careless disposal of tuberculous sputum. Damp soil fosters tuberculosis; model tenements built on good soil with proper drainage will go far to stamp out this disease. Overcrowding of all institutions as well as dwellings should be avoided. The creation of schools of forestry would give useful and healthful employment to a number of men as well as rendering the regions more healthful.

Hydrotherapy in Pneumonia.—Simon Baruch considers that the judicious application of hydrotherapy in pneumonia fulfils all the therapeutic indications by meeting all the depreciating conditions which lead to a fatal termination. Only one condition is unaffected by this treatment, namely, resolution. He has observed crisis in only about twenty-five per cent. of cases. The local course of the disease appears to be unchanged. Resolution proceeds slowly but surely. The patient has a normal temperature, pulse, and almost normal respiration from five to twenty days before all signs of consolidation have disappeared. The special conditions encountered in pneumonia, which Baruch believes are successfully met by appropriate hydrotherapy, are: (1) To fortify the nervous system; (2) to sustain the heart; (3) to strive for elimination of noxious products arising from the life and death of the diplococcus; (4) to render the patient comfortable by reducing high temperature, deepening inspiration, and producing sleep. Flexibility is a notable quality of hydrotherapy. By various procedures, changing of temperature and duration, we may adapt the application of water to the most opposite conditions for the fulfilment of these indications.

Neuropathic Joints.—Sidney A. Lord takes up first the classical examples of true nervous arthropathies, those of tabes dorsalis and syringomyelia, which occur in from five to ten per cent. of all cases of the former, and ten per cent. of the latter disease. There are two principal types of change, atrophy and hypertrophy, the latter being the more common. The author holds that several factors undoubtedly can and do exist in the etiology of both high and low grades of the arthropathies, but the only absolutely constant elemeut is the nervous system, which acts directly by influencing nutrition, and indirectly by causing ataxia. Other joint affections which may be spoken of as neuropathic, are hydrops articulorum intermittens, the location of which is more usually in the knee; and the acroarthritis of Hutchinson, in which the terminal finger articulations become typically wobble-jointed.

Suppurative Pericarditis and its Surgical Treatment.—Charles B. Porter concludes that: (1) pericardotomy is indicated in all cases of suppurative pericarditis. (2) Because of the uncertain and varying relations of the pleura, and because of the anterior position of the heart, whenever the pericardial sac is distended by fluid, aspiration of the pericardium is a more dangerous procedure than open incision, when done by skilled hands. (3) Incisions of the pericardium can be done quickly and safely by resection of the fifth costal cartilage, and in many cases under local anæsthesia. (4) In many cases of serous effusion oper incision without puncture will offer less risk and speedier cure than aspiration. (5) The method and detailed technique of the writer, proposed in 1897, have been followed out by the majority of recent operators.

Septic and Gonorrhœal Joints.—Charles A. Porter says that the object of his paper is to show: (1) That the gonococcus alone can cause arthritis, which, without the presence of other organisms, may be purulent. (2) Gonorrhœal arthritis occurs not only in acute gonorrhœa, but in the chronic or latent stages, which persist much longer than is commonly believed. (3) The signs of such chronic infection in the male and female are often slight, and disregarded or overlooked by the patient and physician. (4) In consequence, not a small proportion of cases are diagnosed as articular rheumatism which are really of gonorrhœal origin.

To What Extent Does the "Rheumatic and Gouty Diathesis" Enter into Traumatic and Other Diseases of the Joints?—By William H. Porter.

Medical News, October 20, 1900.

Treatment of Typhoid Fever.—Stephen Smith Burt declares that on account of the personal equation to be considered in typhoid fever there can be no stereotyped method of treatment. The individual power of resistance and the probable extent of the infection must be estimated. The patient should always be put to bed at once and there be kept till advanced convalescence. The writer is inclined to a fluid dietary for these cases. Water should be freely administered. There must be plenty of fresh air. The mild cases will end in recovery without any medication. The malignant infections commonly will result in death in spite of all treatment. The nervous symptoms are of more importance than is the temperature. Some form of cold-water application is more soothing to the former than any other treatment, although this need seldom be an actual tub bath. A sponge bath of one-third alcohol and two-thirds cold water thoroughly carried out, in the majority of instances, will accomplish the desired results with considerably less expenditure of strength of the part of the patient. The safest intestinal antiseptic remedies, if any are to be tried, are mild laxatives, and for moving the bowels ordi-

narily a rectal injection is best. In hemorrhage ice to the abdomen and gr. ¼ doses of powered opium every fifteen minutes are efficacious. When the bowels move more than three or four times in twenty-four hours, subnitrate of bismuth in large doses, alone or with a little morphine, will often be all that is necessary. Strychnine, ammonia, alcohol, and ether are reliable supporting remedies. Caution should be observed in regulating the diet in convalescence.

Increasing the Therapeutic Value of Cod-Liver Oil by the Addition of Free Iodine and Free Phosphorus.—Louis J. Lautenbach discusses the history of the production of cod-liver oil. He gives Möller's classification of the components of cod-liver oil: Hydrocarbons; oxygen compounds; combinations of oxygen compounds; oxygen cyclo-compounds; halogen compounds; sulphur compounds; nitrogen compounds; proteids; ptomains and leucomains; toxins and antitoxins; ferments. This oil has alterative, tissue-building, tissue-repairing, and nourishing qualities which are wonderful. But the modus operandi cannot be clearly explained. Osmosis and endosmosis are more rapid than with any other known oil. Its emulsion is also very rapid. It has wonderful nerve building properties—perhaps due chiefly to the phosphorus; its alterative effects are probably due to the iodine and bromine. Some years ago, the author began to contrast the effects of the new oils as compared with the same oil fortified by the additions of iodine, bromine, and phosphorus. As the result of experiments the author, aided by his druggist, has produced a preparation called "oleum morrhuæ iodi-phosphoratum." In each tablespoonful of this oil are gr. $\frac{1}{100}$ of pure free phosphorus and gr. $\frac{1}{2}$ of pure free iodine. This oil is less repulsive to taste and smell than are others, is more easily digested, and less liable to be followed by eructations. It is ordered to be taken on retiring, dose one tablespoonful, and followed by a taste of lemon. Its use has been followed by the most gratifying results.

Progressive Pernicious Anæmia.—By Alfred Stengel.

The Lancet, October 13, 1900.

Dacrocystitis Aggravans Resembling Tumor of the Face.—Kenneth Scott saw in Egypt a woman aged seventy-five years, who presented on the left side of the face a tumor which on examination proved to be a double dacrocystitis attaining on the left side enormous proportions. Both the upper and lower left eyelids were so inflamed and œdematous that the palpebral fissure could not be opened, but later the globe of the eye was found to be intact. There was, in addition, a large tumor, vertically oval in shape, which extended from the region of the eye to the angle of the mouth, close to the perpendicular mesial line of the face. It encroached upon the eye so as almost to conceal it, filling up the surface depression over the orbital cavity and extending laterally outward to be in line with the external canthus. Its lower limit was marked by the fold of skin running between the side of the nostril and the corner of the mouth, and the level of its surface lay at a considerable distance forward in front of the bridge of the nose. The tumor had a well-defined border and was wholly sessile; its surface was smooth and even, and showed no signs of redness. Although it was extremely tense there was a distinct sense of fluctuation present, and apparently some degree of pointing toward its lower and outer aspect. The surrounding tissues were thickened and indurated, but only in the eyelids was there any outward evidence of acute inflammation. There was much local pain but no general disturbance of the system. On the right side the condition was of minor degree and was removed by cutting the lower canaliculus and following the ordinary routine. On the left the tumor was incised on its outer edge and pus escaped, allowing complete collapse of the swelling. Twelve days later the lower canaliculus was slit and a style inserted into the lacrymal duct. The sac forming the swelling was found to be a multilocular one. A counter opening to permit free drainage was made and cure resulted in five weeks.

Bilateral Resection of the Superior Cervical Sympathetic Ganglion of the Sympathetic for Glaucoma.—H. W. Dodd repeated the operation originally described by Jonnesco, on a woman aged sixty-two years, and thus describes it. An incision about four inches in length was made along the line of the anterior border of the right sterno-mastoid muscle, beginning above at the level of the angle of the lower jaw, through the skin and fasciæ. The anterior border of the sterno-mastoid muscle was then exposed, its fascia divided. The common facial vein was ligatured and divided. The fascia below the sterno-mastoid muscle was then torn through and the sheath of the great vessels of the neck was opened. The artery and vein were carefully dissected apart and the vagus nerve was then searched for and found. It was then drawn forward by a retractor, together with the carotid artery, while the internal jugular vein was held backward by another retractor. The cord of the cervical sympathetic nerve with the superior cervical ganglion was then found in the fascia at the bottom of the wound, from which it was carefully dissected out. The ganglion was seized in a strong pair of forceps and pulled forcibly downward with a twist so as to tear out the nerve from as high up as possible. The nerve was then cut off at the lower angle of the wound and about one and a half inches of its length were removed, including the ganglion. The operation was then repeated in exactly the same manner on the other side of the neck. The wounds were closed with separate silk stitches and a wet gauze dressing was then applied. The anæsthetic employed at first was ether, but it was found necessary to change this to chloroform for the second operation on account of the engorgement of the veins of the neck produced by the ether. The effect of the operation on the glaucoma could not be told until after the lapse of several months' time.

Two Illustrative Cases of Sinus Pyæmia with Unusual Results.—In the first of James Kerr's cases which were treated by operation and anti-streptococcus serum a fatal result occurred and autopsy showed the following condition: Extension of the thrombus back from the obliterated part of the sinus and up the petrosal sinuses, general discoloration of bone, erosion and purulent lymph about the jugular foramen, several perforations punched out of the vein wall, and communication from the floor of the tympanum through the jugular dome, by which route infection seemed to have spread. A second case in a child aged five years also resulted fatally. The mechanism of these cases is usually a chronic suppurative otitis with extension to the mastoid antrum and cells, which discharge freely until suddenly, either from increased thickening of the mucous membrane or from slow thickening of the bone, the antral passage becomes blocked and discharge ceases. The first signal of danger—pain—follows, with violent inflammation from the retained pus, which often in children breaks its way through the ununited squamoso-mastoid fissure, but in others more often finds its way into cerebral, sigmoid, or cerebellar fossæ.

British Medical Journal, October 13, 1900.

The Medicinal and Dietetic Treatment of Heart Failure in the Aged.—F. W. Forbes Ross in his summary of this subject says that digitalis stimulates the vagus, and depresses the reflex action of the cord and motor nerves. It acts by prolonging the cardiac diastole and increases the peripheral resistance, is irregular in results, is cumulative, is irritating to the alimentary canal, and induces suppression of urine in the aged. Strophanthus does not stimulate the vagus, prolongs the cardiac systole, renders the nervous system hyperæsthetic primarily, and does not have any effect on the peripheral circulation till long after it has increased the force of the cardiac systole, is non-cumulative, is not any more, if as much, an irritant to the alimentary canal than digitalis, acts regularly, and can be given with benefit for very lengthened periods, even up to four years continuously, with only good effects. The nervous system is affected adversely only when strophanthus is combined with a mineral acid. It does not act like digitalis on the heart as it can be given at once even after digitalis has produced ill effects; yet these effects pass off while the patient is actually taking strophanthus. The drug next in value for a senile heart is mercury. Iodide of potassium is praised as a diuretic and cardiac tonic. Nitrates are recommended. Phosphates and hypophosphites of lime, sodium, potassium, and iron, cod-liver oil, and bone-marrow for those who cannot take oil, will be found most useful. Nux vomica serves to initiate the muscular contraction which strophanthus makes more decided. To do this efficiently and continuously without using up the cardiac reserve necessitates a highly nutritious and easily assimilated dietary. The myosin is obtained from raw minced steak extracted by cold 0.5-per-cent. sodium-chloride solution and then curdled out. It can then be put into pudding, milk, or be made into meat panada. Much can be done for the heart that is regarded as worn out.

The Treatment of Gouty Eczema.—Gilbert John King Martyn believes that in the vast majority of cases of eczema gout will be found as the fundamental dyscrasia. The types of eczema met with in gout are roughly the

acute dry, the acute moist, the chronic, and the latent. By the last is meant a burning, itching, tormenting sensation beneath the skin; nothing is visible on the surface. It is one of the commonest complaints of the gouty, and often renders their life intolerable. It is usually worse when the patient is in bed, and nearly always associated with gouty acid dyspepsia. The treatment consists in enforcing a rigid dietary. Bismuth and alkalies must be freely given. For the burning and itching, a lotion or ointment containing carbolic acid is best. One of the most essential points in the treatment of gout and gouty eczema is the production of a healthy action of the skin and the avoidance of extreme loss of heat with sudden chilling of the surface; while, at the same time, irritation is kept at a minimum. As little change as possible should be made in the winter and summer clothing. The underclothing must not be varied. The best material for this is undoubtedly cotton in the cellular woven form or in the form of Lahmann's cotton-wool clothing. Climate is of great importance, the best being one which is equable and fairly bracing. As to diet, it should be a typical gouty diet, with the minimum of proteid and starchy foods and all those articles which produce an acid fermentation. The writer believes the drugs which are of real value to be those which benefit dyspepsia and increase the alkalinity of the blood, such as bismuth, the alkalies, and the bromides. Antimony will at times relieve the itching, though sometimes morphine is necessary. Lotions and dusting-powders as well as the use of water are then discussed.

The Subcutaneous Administration of Oxygen.—William Ewart declares that no conclusions can be based upon so limited an experience of these two methods—subcutaneous infusion of solutions of peroxide of hydrogen and subcutaneous injections of oxygen gas—of supplying oxygen locally to the systemic circulation, nor would he venture at this stage to recommend their employment except in urgent conditions when oxygen cannot be inhaled. The two series of observations show that there may be set up a local oxygen emphysema of the areolar tissue without any evil result, and that the gas will be gradually absorbed, though the process is slow. The diluted hydrogen peroxide infusion probably presents less risk than the other method, though the oxygen-gas injection is easier to carry out. The clinical value of the subcutaneous method as a general stimulant has yet to be made out.

A Discussion on Serum Therapy.—T. J. Bokenham, after discussing this subject in general, takes up in particular, first: antidiphtheria serum, which as a curative agent has quite fulfilled the expectations of most physicians. As an immunizing agent, the author's personal experience, extending to nearly five hundred inoculations, is altogether in its favor. Antistreptococcus serum rapidly deteriorates, so the results are not likely to be uniform. Antipneumococcus serum is not bactericidal as pneumococci grow readily in it. The chief difficulty in its clinical use arises from the great number of bacteria present in the lung exudation, and from the fact that the action of the serum seems limited to preventing the entry of the organisms into the blood-vessels.

Some Work Bearing Upon the Preventive Treatment of Oxalate of Lime, Gravel, and Calculus.—Lindley Scott states that it is certainly known that oxalate of lime contributes largely toward the formation of calculus, especially renal calculus. The urine which deposits calcium oxalate is generally reported as acid, of an increased specific gravity, and frequently with a high proportion of urea and other solid constituents. The prolonged administration of small doses of magnesium, say gr. xl. of the sulphate, given in the afternoon and at bedtime, in a well-diluted solution or combined with some mild diuretic, would seem a suitable treatment. Attention to general health, regimen, and diet must be observed.

Treatment of Asthma and Hay Fever.—Ernest Kingscote believes there are three pretty constant factors in cases of asthma of long standing—cardiac dilatation, acute vesicular emphysema, and chronic congestion of the liver. The conditions must be dispersed in addition to any other causes in order to cure the patient. Having ascertained the vagal or sympathetic irritation, it should be removed. Cardiac dilatation is best reduced by the Schott treatment and emphysema by appropriate breathing exercises. The patient should be in the open air as much as possible.

Eight Cases of Sausage Poisoning.—Lank describes an epidemic of a disease affecting three adults and five children, which was at first thought diagnosed as diphtheria but was afterward found to be caused by the eating of imperfectly cured sausages. Poisoning from this source (botulismus or allantiasis) is to be differentiated from that due to the use of putrefying meat, and a specific organism, the bacillus botuliuus, has been isolated and found to generate a toxin resembling the poisons of tetanus and diphtheria in its chemical composition. The course of the disease is protracted even in the lighter cases, the first symptoms not appearing for twelve to twenty-four hours. They are then ushered in by general malaise, nausea, vomiting, and diarrhœa, followed by dyspnœa and prostration. A characteristic effect of the intoxication is the decrease in all the secretions with the resulting dryness of the skin and mucous membranes. As a consequence the mouth presents aphthous ulcers and the throat is filled with erosions, red patches, and a grayish membrane frequently resembling that of diphtheria, while the condition of the intestinal canal and air passages produces obstinate constipation and hoarseness often accompanied by a croupy cough. Eye symptoms are typical and comprise cloudy vision, chromatopsia, evanescent amaurosis, and diplopia; ptosis is a constant and pathognomonic sign of the intoxication. There are no central manifestations, but dysphagia and aphasia of peripheral origin are observed; there is also no fever, though the pulse grows rapid and weak. Death may not occur for some time, and then be due to the inanition and marasmus, or may follow in from eight to ten days owing to paralysis of respiration, no typical post-mortem appearances being produced.

A Case of Purpura Hæmorrhagica.—Nehrkorn describes the case of a twenty-six-year-old laborer who was suddenly taken with severe epistaxis followed by extensive subcutaneous hemorrhages, hæmaturia, and bleeding from the oral mucus membrane. These symptoms were accompanied by great prostration which speedily becan e extreme in consequence of the uncontrollable loss of blood from mouth, kidneys, and gastro-intestinal tract. Finally, delirium, restlessness, and coma were succeeded by death four days after the first symptoms. The hæmoglobin was found reduced to twenty per cent., and the red blood cells to one and a half millions. At the autopsy there were found extensive hemorrhages into all the viscera with moderate endocarditis of the aortic and mitral valves and a narrow aorta. The case is interesting in that its fulminating course with the extensive hemorrhages and pustule formation very greatly simulated hemorrhagic variola, and though the history excluded this, the picture of the malady was essentially that of an infectious disease.

The Position of the Stomach in Chlorosis.—Otto Rostoski controverts the view of Meinert and some other authors who maintain that chlorosis is always accompanied by gastroptosis, or even go so far as to say that the dislocation of the stomach precedes, and through the resulting nervous derangements actually produces the blood dyscrasia. The writer's observations extend over a series of fifty cases of chlorosis, in thirteen of which a state of gastroptosis was found which seemed, however, more directly referable to a too early use of the corset, a circumstance especially meriting attention in the frequency with which distended loops of intestine are pushed before a stomach undergoing artificial inflation for purposes of diagnosis and a dilatation is thus simulated. In the writer's opinion faulty conclusions are often reached owing to this source of error, and several

different methods for determining the stomach boundaries should always be resorted to before a positive diagnosis is made.

The Question of Traumatic Spinal Disease.—M. Oberst attacks the position of Kümmell, who believes in traumatic spondylitis, *i.e.*, a rarefying ostitis beginning weeks or months after slight injuries, and leading to a greater or less loss of substance, and maintains that all such cases are really compression fractures. Injuries of this nature are much more frequent than is supposed, and inasmuch as they may be due to slight trauma and give but few subjective or objective symptoms are very easily overlooked. Still a certain degree of violence is necessary to produce such a lesion, and in accident cases when kyphosis follows in spite of the insignificant nature of the injury, tuberculous disease is to be assumed. The term traumatic spondylitis is misleading and may advantageously be replaced in doubtful cases by the designation "traumatic kyphosis."

The Treatment of Spina Bifida.—C. Hennemann reports an instance of this defect in which the result of treatment was so happy as to discount the usually pessimistic view taken of such cases. At the time treatment was begun the tumor was the size of a child's head, and its covering as thin as paper, threatening to burst at a touch. The lower extremities were anæsthetic and both bladder and bowel completely paralyzed. The fluid was aspirated on three occasions, 1,550 c.c. being obtained, and each time 30 c.c. of Lugol's solution were injected into the sac. After the third operation no reaccumulation occurred, and in the course of time all the secondary symptoms disappeared without any indications of a possible relapse.

The Occurrence of Carcinoma.—Reiche finds that the carcinoma statistics of Hamburg show what has been found true in other localities, viz., that during the last thirty years the mortality from cancer has been slowly but steadily rising, that the increase affects the male population more than the female, and that the average age of the fatal cases is growing less. By contrasting the figures taken before and after certain radical sanitary and other reforms were instituted in the city, he arrives at the conclusion that the local occurrence of carcinoma is independent of the nature of the water supply, the density of population, the comparative altitudes of different parts of the city, and conditions of poverty or affluence.

The Effect of Petroleum on the Diphtheria Bacillus.—J. Papasotirin made numerous experiments with a view to determine whether the use of petroleum in diphtheria was justified by the facts. The agent was applied to growing colonies of the bacilli in various ways with the invariable result that the plates so treated flourished just as vigorously as the control growths. Any remedial effect of petroleum in diphtheria is therefore independent of a germicidal action on the organism.

Deutsche medicinische Wochenschrift, October 4, 1900.

Black-Water Fever.—In a preliminary report Hans Ziemann affirms his inability to find a specific organism for this disease as stated by Yersin. In certain malarial districts there is found among those who have already suffered from a malarial infection a disposition to attacks of black-water fever. In general this is increased proportionately to the number of previous malarial infections, and is greatest among those having the hemorrhagic diathesis or who have been weakened by hardships, though it also occurs in healthy individuals of good antecedents. The small parasite of the tropics, or the æstivo-autumnal form, seems most predisposing, though apparently differences in virulence due to varying conditions in different localities play an important rôle. In regard to the positions that black-water fever is purely a result of quinine poisoning, or, on the other hand, that it is a special form of malaria characteristic of certain localities, it may be said that it is observed: (1) Following a new malarial infection in which no quinine has been given; (2) following malaria treated with quinine; (3) following the administration of quinine to those who have formerly had malaria but are at the time free from the parasites; (4) in those who have suffered from a previous attack of black-water fever but have not recently taken quinine and whose blood does not contain any parasites.

Dysentery and its Specific Cause.—W. Kruse warns against the belief that dysentery as an epidemic disease has died out, and cites several localities in Germany which have suffered greatly from its ravages in recent times. The disease as found in Egypt and the tropics is usually of amœbic origin, but study of an epidemic at Laar has brought to light an organism which the author thinks is specific, and which owing to its cultural and other affinities he would place in a trinity with the typhoid and colon bacilli. In appearance it differs markedly from the typhoid bacillus, being shorter, thicker, and devoid of flagella, but its biology and manner of growth apparently indicate a close relationship between the two. An important reaction serving to distinguish the new organism from the group usually termed collectively colon bacilli is its inability to produce fermentation in grape-sugar media. It is not specific for animals, but is agglutinated by the blood serum of dysenteric patients and remains unaffected by that of healthy individuals.

Pneumonia through the Meningococcus.—J. Bernheim describes in detail the clinical course and pathological findings in a case of pneumonia running so rapidly fatal a course as to make a general systemic infection seem probable. This was found not to be the case, however, but the fluid from the lungs contained large numbers of diplococci which gave all the microscopical and biological evidence necessary to identify them with Weichselbaum's meningococcus intracellularis.

The Conversion of Proteids and the Excretion of Sugar.—By Th. Rumpf.

Berliner klinische Wochenschrift, Sept. 24, 1900.

Medical Supervision of Cures for Obesity.—E. H. Kisch says that in attempts to reduce bodily weight, care should be taken to avoid all measures which tend to weaken the patient's strength and especially heart action. There should be a regulation not only of the amount of food and drink, but also of the general mode of living and the patient's former habits, all of which must be based on a careful consideration of each individual case. The amount of exercise may be regulated by means of a pedometer, and the number of daily steps carefully increased; in due time he may be allowed to climb hills, but the heart should be carefully watched.

Treatment of Dropsy by Means of Cupping-Glasses.—K. Miura has devised a cupping-glass for the purpose named. To the glass is attached a rubber tube, the whole being filled before use with a decinormal salt solution. Superficial incisions are made in the dropsical part under strict antisepsis, care being taken not to draw blood, and the apparatus is then applied. Flow of the salt solution from the tube is then induced, and the author has found that it is possible to draw by these means considerable quantities of fluid from the tissues.

Simple Primitive Hyperchlorhydria (Digestive Chlorhydric Hyperæsthesia) and Continuous Gastric Hypersecretion.—Luigi Sausoni quotes Linossier as believing that under the syndrome of Reichmann the following pathological types should be accepted: (1) Primitive gastrosuccorrhœa without pyloric stenosis; (2) primitive gastrosuccorrhœa with consecutive spasmodic pyloric stenosis; (3) primitive gastrosuccorrhœa with ulcers and consecutive anatomical pyloric stenosis; (4) gastrosuccorrhœa by retention following a pyloric stenosis. The surgeons Carle and Fantino, especially, not being able to deny absolutely the existence of a primitive gastrosuccorrhœa not accompanied or followed by pyloric stenosis, attribute the greatest importance to alimentary stasis, consecutive to a stenosis of the pylorus, spasmodic or real. The prevalent opinion today relative to the origin of continuous gastrosuccorrhœa accords almost completely with that expressed by the author in 1888. He believes that the cause of the syndrome of Reichmann consists in alimentary stasis due to obstruction, functional or otherwise, of the pylorus. Nevertheless, the primary cause for a certain category of cases is,

the author believes, not hyperchlorhydria but hyperæsthesia of the gastric mucosa, admitting, for another category, that the pyloric spasm depends on anatomical lesions which escape clinical diagnosis, such as small ulcerations, etc. He does not wish to deny absolutely the existence of a secretory trouble—primitive and fundamental in the genesis of continuous gastrosuccorrhœa, but he adds that among several thousand patients with gastric trouble, whose stomachs he has examined from a functional point of view, in every one of whom the symptoms indicated the existence of a continuous gastrosuccorrhœa, he has always found in the stomach even after fasting remnants of food of a quantity greater or less.—*La Presse Médicale*, September 29, 1900.

Extra-Buccal Alimentation.—According to M. Ewald, extra-buccal alimentation cannot completely replace buccal alimentation; it cannot suffice for a long time for the exigencies of nutritive changes; in the majority of cases, an alimentation exclusively extra-buccal produces from the beginning a subnutrition; this form of feeding may, however, for a short time, in enfeebled individuals whose nutritive metabolism is diminished, increase the nitrogenous changes, and even cause an increase in weight; its best results are seen when used transiently, or when employed only as an adjunct to buccal feeding; in the majority of cases, nutritive enemata ought to be preferred to subcutaneous injections. Discussing the same subject, M. Leube formulates the following: (1) Per rectum: albuminoids which can be administered are preparations of peptone (60 gm.) or eggs (3+3 gm. of salt). The vehicle should be 300 gm. of milk. Carbohydrates can be given in doses of 15 to 20 gm. for 300 gm. of liquid, but starches are to be preferred—15 to 20 gm. to 100 gm. of water or milk. Fat is not suitable for rectal enemata. The value of each of these enemata is from 500 to 650 calories, and they should be given twice a day. (2) Fat can be employed for subcutaneous injections, the dose being from 50 to 100 gm.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, September 27, 1900.

Disinfection by Formacetone.—Eugène Fournier gives the following conclusions on this subject: Perfect disinfection can be accomplished only by gas or vapor. Of all the substances employed, formacetone can be considered the most energetic disinfectant and a very active, if not the most active, insect destroyer. The proportion of the vapor necessary to use is in direct ratio to the size of the object to be disinfected. It is necessary to dampen the object first by a projection of acetone vapor. The vapors of formacetone are not inflammable. The projections ought to be made under a pressure of 4 kilos., which ought to be maintained during the whole process. The duration of contact of the disinfectant vapor is to be in inverse proportion to the temperature. In places where there is no apparatus for disinfection, clothing is sterilized by immersion, and after rinsing and drying, an iron will restore the former appearance. Surgical instruments are sterilized by formacetone in a very practical manner at 45° C. in a special sterilizer, and they undergo no alteration.—*Gazette des Hôpitaux*, September 29, 1900.

A Case of Sacro-Coxalgia.—E. Leclerc sums up the characteristic symptoms of this affection after describing a case: Pain distinctly limited to the level of the sacro-iliac space; elevation of the pelvis on the affected site (measured by the elevation of the anterior superior iliac spine); shortening, both apparent and real, of the leg; increase of the distance which separates the middle of the sacrum—not the sacral crest—from the anterior superior iliac spine; slight atrophy of the muscles of the buttock and of the thigh.—*Le Bulletin Medical*, September 29, 1900.

Archives of Pediatrics, October, 1900.

Report of a Case of Pulmonary Stenosis.—Samuel McC. Hamill reports a case in a boy aged six years. Auscultation of the heart revealed a rather rough, blowing, systolic murmur heard over the entire precordia, and to some extent over the entire anterior portion of the left chest, with its point of maximum intensity in the second left interspace. At this point it was superficial, very loud, low-pitched, almost grating in character. This very marked loudness was limited to an area about the size of a half-dollar, corresponding to the pulmonary region. Over the portion of the heart extending to the right of the sternum was heard a peculiar, loud, flap-like, systolic sound, suggesting the loud first sound of mitral stenosis. There was no accentuation of the pulmonary sound. As a matter of fact, it was almost inaudible. The heart's action was rather rapid, strong, and regular. By an exclusion of other lesions, a diagnosis of pulmonary stenosis was reached. The lesion is uncommon, and its existence, as in this case, without evidence of venous stenosis is rare.

Atresia of the Larynx due to Traumatism, the Result of Faulty Intubation.—W. P. Northrup submits a specimen, the last case of intubation seen by the late Dr. O'Dwyer. The tubes used in this case were of the latest approved pattern; the technique was that of a beginner and proved faulty. Imperfect tubes and imperfect technique constantly worked against the success of intubation and gave Dr. O'Dwyer great uneasiness of mind. Each brought reproach upon the operation; each meant traumatism to the larynx; each worked to the harm of the patient; each diminished the chances of recovery. The inventor wrote always in the same strain, endeavoring to keep it before the minds of the medical profession that the operation should be done by skilled hands and should include proper tubes.

Acute Nephritis following Influenza.—Rowland Godfrey Freeman concludes that: (1) Although albuminuria is fairly frequent with influenza, nephritis is a rare complication. (2) The nephritis complicating influenza is clinically of the acute hemorrhagic type and morphologically shows toxic lesions. (3) It apparently attacks children more often than adults. (4) The kidney disturbance may appear a few days after the acute symptoms of the influenza, or as long as a month later. (5) The prognosis is good.

A Case of Suppression of Urine Apparently due to Ascaris Lumbricoides.—By Frank Vander Bogert.

Congenital Cardiac Malformation with Endocarditis and Anuria.—By A. C. Cotton.

The Edinburgh Medical Journal, October, 1900.

The Clinical Forms and Pathological Anatomy of Spinal Syphilis.—R. J. Williamson thus classifies the clinical forms of the disease: (1) Symptoms of compression of the spinal cord or nerve roots may be produced by syphilitic disease of the vertebræ, syphilitic caries, necrosis, gumma, exostosis, periostitis, or osteitis. (2) In another very rare form there are symptoms of chronic meningitis without indications of involvement of the spinal cord. (3) Meningomyelitis is the most common form of spinal syphilis. (4) Acute syphilitic paraplegia (acute syphilitic myelitis). (5) Erb's syphilitic spinal paralysis. (6) Paraplegia with combined degeneration in the posterior and lateral columns. (7) Gumma of the spinal cord or meninges. (8) Anomalous forms. The author gives nine. (9) Locomotor ataxia. Sir William Gowers thinks that after a deduction is made for possible accidental coincidence, there is still a causal relationship between this disease and syphilis in one-half to three-quarters of the cases. The pathological changes produced by syphilis may be divided into three classes: (1) Those which indicate syphilis most clearly—gummata, gummatous infiltration of meninges or cord, etc.; (2) changes suggestive but not conclusive of syphilis—disease of the blood-vessels, endarteritis and periarteritis, endo- and periphlebitis; (3) changes secondary to the vascular disease; thrombosis of spinal vessels, or complete or partial obstruction of the vessels from thickening and disease of their walls. It is to be hoped that future bacteriological research will lead to the discovery of a characteristic micro-organism in syphilitic lesions.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

OPENING OF THE SESSION—NOTES OF INTRODUCTORY LECTURES—LORD LISTER'S HUXLEY LECTURE—THE GOVERNOR OF LAGOS ON MALARIA—PROFESSOR POORE ON THE LECTURE SYSTEM—DR. PENROSE ON THE LONDON UNIVERSITY—PROFESSOR M'FADYEAN ON EXPERIMENTAL RESEARCH—THE PLAGUE—TYPHOID—THE LATE DR. SAVAGE.

London, October 5, 1900.

The opening of the winter session is important enough to demand attention even amid the distractions of a general election and the excitement of war news. Dinners, conversazioni, and prize distributions have in some cases displaced the old-time introductories; but several of the schools have continued their lectures, which now fulfil an important function, though one somewhat different from that of the last generation. But what can a correspondent say about half a dozen high-class addresses delivered during the week? It is impossible to summarize them, and space interposes barriers against criticism. I will therefore give you only samples of what I hear about them.

Lord Lister's was naturally expected to be something out of the common. He gave the "Huxley Lecture," which was founded to commemorate the fact that the emi-

nent physiologist received his medical education at Charing Cross Hospital. It is delivered biennially and serves as an introductory at that school on alternate years. Lord Lister's is the third of this series, the preceding ones having been given by Sir M. Foster (1896) and Professor Virchow (1898).

Lord Lister's subject was his early work leading up to the antiseptic system, and he was induced to take it by the desire of those who asked him to give the Huxley lecture that he should deal with his own work. He objected on the ground that what he had done had for the most part been published, but yielding to friendly pressure he took up his early efforts as those least known. So we had a charming bit of semi-autobiography from the time when his father, who had done so much to improve the microscope, equipped him with a first-rate instrument and sent him to study at University College, up to that when Pasteur's demonstration that putrefaction is due to microbes was made. For this his mind was quite prepared by the researches he had made, and the problem became, how to exclude microbes from wounds. As he said in concluding, "It has been since shown that putrefaction is not the only cause of mischief in wounds—in other words, it has been proved that there are microbes which produce poisons that do not occasion unpleasant smell. But the principle that first guided me still retains, I believe, its full value, and the endeavor to apply that principle so as to insure the greatest safety with the least attendant disadvantage has been my chief lifework."

At the School of Tropical Medicine, Sir William MacGregor, M.D., governor of Lagors, discoursed among other things on malaria and the mosquito theory. Judging from personal experience, he said, it seemed to him that dysentery caused more deaths in the tropics than any other disease; but to the European the most important is malarial fever. He proceeded to show that the mosquito on the west coast of Africa must be reckoned with at every turn. To meet the position hospital wards must be painted with colors that will show up the mosquito; doors and windows should be of fine gauze wire netting, and all beds provided with mosquito-proof curtains; all water-tanks, wells, reservoirs, and even flower pots must be protected with wire-net covers, and any other breeding-place near a hospital rendered impracticable for the insects. In hospital discipline it will be an offence to allow a patient to be bitten. In the tropics Sir William MacGregor would have the subject of malarial genesis put before the public in its simplest form and taught in all the schools. Prizes should be given to the best scholars in the malarial class. Ladies who understood the theory would not dine in low dresses; nor would gentlemen sup with their ankles covered only by thin silk socks. The governor of Lagos gave some interesting details of personal experience with anopheles. One statement he made was that this mosquito is not exclusively a night feeder, but will at times bite in the day, though he prefers dusk or dark.

At University College Dr. Poore, as professor of medicine, deliberately addressed himself to those who having gone through their anatomical and other scientific work were about to enter the wards to study medicine proper. There being always a doubt how near the methods of the laboratory approached to those of nature, he argued that the discoveries of the former must be checked by observation of the latter. The word "science" was often used in too narrow a sense, especially by narrow-minded people, but practice afforded abundant opportunities for the best scientific work. Harvey found many facts among his patients to support his doctrine of the circulation, and other discoveries made by comprehensive observation of the sick were confirmed by bacteriology. Practice is often in advance of theory as seen in inoculation and vaccination, to which our eyes are only beginning to be opened. The housewife bottling her fruit anticipated Pasteur; the shepherd with his bread, cheese, and raw onion, guided by natural appetite, selected a food which the physiological chemist at a later age finds to be a judicious blend of "proteids, carbohydrates, fats, antiscorbutics, and antiseptics"; Emin Pasha used mosquito curtains as a protection from "miasmatic exhalations." We must not, then, lightly abandon established practices at the bidding of half-educated theorists, but theory and practice must go hand-in-hand.

Dr. Poore then congratulated his hearers on the nearly completed hospital which will soon be an ornament to the district, and for which the name of Blundell will in future be coupled with that of Guy. About two-fifths of the hospital is ready for occupation. He then defended the system of lectures, though many people had thought them useless in these days of text-books. He had himself spent no time more profitably than in attending the lectures of the late Sir William Jenner, who made no attempt at oratory and no display of learning, but whose style was that of an honest man, brimful of knowledge which he was eager to impart. The mere reader with his nose in his manuscript might be replaced by the phonograph, but the true lecturer is in sympathy with his hearers, knows when they are interested and when he has failed to make himself understood. The lecturer could treat his subject with more freedom than the text-book and give a comprehensive view of the whole subject. In these days of specialism it is possible for a student's knowledge to be "scrappy"—such as might be that of the aphis to the rose-leaf it feeds on. In specialists' books rarities naturally assumed too much importance to serve as mental pabulum for students. The child who complained that in its Noah's ark "the beetle was as broad in the back as the elephant" might have passed a similar criticism on a treatise lately read on skin diseases, written by fifteen different dermatologists, but which had not the word "itch" in the index.

The reconstitution of the London University was mentioned in several of the addresses and hopes were expressed for its future—hopes which are doomed to disappointment unless great changes are made. The old university was a mere examining-board and its requirements led to cramming to such an extent as to be injurious to the best students.

At St. George's Hospital Dr. Penrose, though he extolled the high standard of its examinations—naturally enough, perhaps, for one who had passed them—hoped that one good effect of the new departure would be to lessen the number of the ordeals a man has to pass before obtaining a degree. He looks forward to the time, not far distant, when a qualification and degree may both be had on passing three or at most four examinations: one at the beginning, one after the scientific part of the curriculum, and one final. This, he said, would meet all necessary requirements and would bring medical examinations into more conformity with those of the other learned professions. How far such a programme differs from that enforced hitherto will be seen when I tell you that the old university insisted on its own matriculation being above the standard of others; after that it required three severe examinations before its lowest degree was obtained. By severe, I mean with regard to book work, for that was ever kept to the front; and however much information might be crammed up for the occasion, you know that such knowledge is a very poor qualification for practice, even if it were not as evanescent as it proverbially is.

Dr. Penrose has evidently felt something of this, for he passed on to remark that it is the part of the teachers to direct the students along the right road, and assure them that it is better to train them to read the sign-posts and find the way than to tell them what is written on the posts and expect them at the journey's end to be able to repeat—not what they have actually seen and heard, but what they have been told they ought to see. Dr. Penrose then passed on to consider some problems concerned with medical education, and strongly urged the claims of laboratory and ward work as both essential and best conjoined.

Professor McFadyean gave an introductory at the Royal Veterinary College in which he showed the valuable results of the experimental methods of investigating disease.

Other gleanings from the addresses would give plenty of sound corn, but for the present the foregoing will suffice.

It is gratifying to see that Glasgow has succeeded in restricting the plague. No new cases since my last. Two deaths occurred during the week—one the baby born in the hospital of the mother who died of plague. There are only twenty-one patients remaining in the hospitals—two doubtful—and the "contacts" in the reception houses amount to only nineteen.

The usual increase of typhoid in autumn has begun. Last week ninety new cases were admitted to the hospitals of the asylum board, bringing the total up to three hundred and twenty-nine. This was an increase of fifty-five over the previous week. There were only eighteen deaths in the week, which indicates a mild type of the disease. Southwark is the most affected district. There about one hundred cases have occurred in the last three weeks. But Dr. Waldo is the energetic medical officer of health there, and every confidence may be felt that nothing he can do is left undone to restrict the outbreak.

Dr. Henry Savage, senior consulting physician to the Samaritan Hospital for Women, died on Wednesday. He took his London M.D. in 1849 and the F.R.C.S. four years previously. You will remember his "Anatomical Illustrations of the Surgery of the Female Pelvic Organs." He was at one time lecturer on anatomy at the Westminster Hospital, but his lifework was in connection with the Samaritan, which he served on the staff, and on the committee after retiring from practice.

The Social Science Association.—The next meeting of the American Social Science Association will be held at Washington, beginning April 16, 1901.

Society Reports.

NEW YORK STATE MEDICAL ASSOCIATION.

Seventeenth Annual Meeting, Held in New York City, October 15, 16, 17, and 18, 1900.

E. D. Ferguson, M.D., of Troy, President.

(Concluded from page 634.)

Third Day—Wednesday, October 17th.

Dr. C. A. L. Reed, of Ohio, President of the American Medical Association, made a forceful speech in favor of the stand taken by the State Association looking toward better organization of the profession. He pointed out that it ought to take but little time and less effort to accomplish a change that had already been effected in sentiment, and that he who interposed prejudice, preference, or prerogative as obstacles to this consummation should be looked upon and treated as an enemy of progress. He had good reason for believing that the medical profession of to-day, the country over, was ready to take any necessary step, through its organized bodies, that it might present a united front to the dawning century.

An Epidemic of Diphtheria Traced to a Milk Supply.—Dr. Chauncy P. Biggs, of Ithaca, presented this communication. He said that in recent years several epidemics of diphtheria had been reported in which it had been clearly shown that they had originated in the milk supply. In a considerable number of these reported cases the strongest evidence of milk infection had been the fact that a large percentage of the patients had been supplied by a certain milkman, although the way in which the infection had actually taken place could not be explained. The fact remained, however, that the epidemic subsided quickly on stopping the sale of this milk. In one epidemic, the liberal users of boiled milk escaped. In the epidemic at Ithaca, one student in a family of eight had diphtheria while the others escaped. Inquiry showed that all of the family had been using infected milk, but all had partaken of it sparingly except this student. From January 31 to March 7, 1900, thirty cases of diphtheria had been reported to the board of health, and the diagnosis in each instance had been confirmed by bacteriological examination. These cases had occurred in twenty-four households in widely separated parts of the city. Of the thirty patients, two died, one a child of seven years, and the other a child of six years. It was soon discovered that nearly half of the cases had received milk from one dealer, and then it was learned that some of the milk sold by this man had been purchased from another. The milk of the wholesaler proved to have been infected. In only three families had it been impossible to trace the milk supply to the source of infection. There had been only fourteen secondary cases.

Management of Diphtheria in Small Cities from a Bacteriological Standpoint.—Prof. Veranus A. Moore, of Cornell University, read this paper. He said that all persons carrying virulent diphtheria bacilli in their throat, whether suffering from the disease, convalescent or immune, might be sources of infection to those with whom they came in contact. A bacteriological examination enabled one to determine those infected among a number who have been exposed, and also when one recovering from the disease might safely mingle with others. Most of the difficulty met with in the efforts of health officers to conserve the public health could be obviated if family physicians would explain to their patients the reasons for the regulations of the board of health, and the need for both the profession and the laity heartily to co-operate. In the recent epidemic at Ithaca, the bacteriological examinations instituted by the board of health had proved useful not only in controlling the spread of the disease but in tracing the source of infection.

The Tonsils as Portals of Infection.—Dr. Julius Ullman, of Buffalo, read this paper. He gave a sketch of the literature, and showed the probability that the tonsils were portals of infection in scarlet fever, rheumatism, and endocarditis. His conclusions were: (1) The normal tonsil had a physiological function protective to the organism; (2) that being in itself often diseased, its physiological function was often impaired, and instead of being protective, it became a nidus for the growth and distribution of pathogenic germs; (3) that many grave infections had their origin in the tonsils; (4) that acute articular rheumatism and the diseases often associated with it, such as endocarditis and chorea, were in the great majority of cases due to the action of attenuated bacteria or their toxins entering the system through the tonsils; (5) that scrofulosis was often associated with disease of the tonsil.

Report of Some Interesting Cases of Infectious Disease.—Dr. De Lancey Rochester, of Buffalo, made this report. Among the cases cited were three of scarlatina without eruption. Another was that of a child of five years, who had been seen by several competent physicians, all of whom had made a positive diagnosis of scarlet fever. Three days after the completion of desquamation the disease had recurred. This case seemed to be unique.

Present Status of Jonnesco's Operation.—Dr. Marcel Hartwig, of Buffalo, was the author of this communication. He urged the use of the name "Jonnesco's operation" for that procedure more commonly known as neurectomy of the cervical sympathetic, because of the classical work of Jonnesco in this field. In speaking of the physiological effects of this neurectomy, the statement was made that these were quite variable, but the most constant was a narrowing of the pupil. Jonnesco had employed this operation chiefly in epilepsy on the apparently erroneous theory that it should prove curative by the production of an anæmia of the brain. The final results in ninety-seven cases were twelve reported cures. This surgeon had operated upon fifteen cases of exophthalmic goitre, with eleven recoveries, and four patients improved. He had also operated in twelve cases of glaucoma, and these cases showed more or less improvement in vision.

The Treatment of Pulmonary Tuberculosis with Special Reference to the Climate of Arizona.—Dr. Clarence G. Campbell, of New York, read this paper (will appear in a future issue.)

President's Address—The Surgical Management of Umbilical Hernia with Large Ring.—Dr. E. D. Ferguson, in this address, said that the method of denudation was easy and satisfactory when the ring was small. In cases of large ring, a successful result had been the exception rather than the rule. The essential feature of those rings which should be classed as surgically "large" was the inability of the operator to approximate the borders of the ring by vertical sutures without placing these parts in a state of constant and considerable tension. In the development of an umbilical hernia, the yielding began just at the point where the umbilical vessels entered the abdomen, and consequently here the hernial ring would be bounded by the linea alba at its upper and lower portions, and below this would be the blended borders of the lamellæ of the rectus. His own method of operating was as follows: A longitudinal incision was made at the border of either rectus. The anterior layer of the sheath was then separated by blunt dissection, and lateral flaps were cut out, care being

taken to make them as long and broad as possible. They were then turned over to the median line and sutured at their free borders by the cobbler's stitch. It was important thoroughly to coaptate the broad surfaces below the ring.

Tuberculosis; its General Etiology, General Pathology, and General Prophylaxis.—Prof. Victor C. Vaughn, of the University of Michigan, opened this symposium on tuberculosis with this paper, the other papers being on surgical tuberculosis. He said that at the outset he wished it understood that the sole cause of tuberculosis was the tubercle bacillus of Koch. The morphology of this germ was not so simple and constant as had been at first assumed. Branched forms had been found in tuberculous sputum, and many investigators had noted the striking resemblance at times to the ray-shaped microorganism of actinomycosis. Under certain conditions not yet well understood, it seemed to be pretty well settled that the tubercle bacillus assumed some forms of growth which pointed to the probability that the specific germ of tuberculosis was not a true bacillus. At least one pseudo-tubercle bacillus had been found not infrequently in butter, and this had led to confusion in the examination of that article of food for evidence of tuberculosis. An organism quite commonly found in cow-dung had been assumed at one time to be the tubercle bacillus, and as this could easily find its way into the milk, it followed that microscopical examination of milk was not an adequate means of proving or disproving the existence of tuberculous infection. The most striking morphological similarity between the tubercle bacillus and the "timothy bacillus" lay in the fact that both organisms assumed a branched form at times. Culturally, however, they were quite distinct. The timothy bacillus had been shown to be practically without pathological effect on man, but Flexner and others had shown that some at least of the pseudo-tubercle bacilli were pathogenic in man. Some observers had assumed that the tubercle bacilli were capable of living quite abundantly and indefinitely outside of the body as saprophytes. This was a mere assumption, however, without scientific basis. There was nothing to show that any one of these saprophytic organisms was ever converted into the pathogenic organism producing tuberculosis in man. The studies of the pseudo-tubercle organisms had not shown the evidence of the true parasitic nature of Koch's tubercle bacillus. The bacillus tuberculosis was thrown off in the secretions of the tuberculous, and then retained its vitality for a comparatively limited period. Even the tuberculous individual was not a source of danger to others, until he began to cast off the tubercle bacillus in his excretions, and even then with proper precautions he might mingle with his fellows without danger to them. It had been shown time and again that the expired air from the lungs, even in the advanced stages of tuberculosis, was free from the specific infection unless it bore particles of mucus or saliva, as happened sometimes in coughing or sneezing, and sometimes in speaking. The transmission of the bacillus was rarely direct, but might be so, as for instance in the performance of ritual circumcision. Inoculation into the skin resulted in the formation of tubercles, and a gradual extension into the lymphatic glands. When the infectious matter was introduced under the skin, the first evidence of infection might be in the neighboring lymph glands. It was probable that diseased tonsils occasionally served as portals of infection. Rabinovitch had shown that animals with initial tuberculosis, and without detectable disease of the udder, might, and often did, furnish milk containing living and virulent tubercle bacilli. This observation confirmed the opinion that he had expressed some years ago, that every dairy cow should be tested with tuberculin. Cattle seemed to be only slightly susceptible to human tubercle bacilli; on the other hand, the bovine tubercle bacillus had been shown to be more virulent than the sputum variety, and that this virulence increased when it was grown in milk. Tuberculosis always began as a local disease, confined for a greater or less period of time to a minute portion of the body. The destructive changes, as a rule, proceeded slowly until the infection became a mixed one. Most of the deaths from pulmonary tuberculosis were directly the result of mixed infection. That the tubercle bacillus had a predilection for pulmonary tissue was shown by the frequency with which the lungs became involved in the lower animals after subcutaneous and intraperitoneal inoculations, yet it was known that many persons lived for years with a local tuberculosis without the lungs becoming involved. The speaker said that our ancestors had freed the race from leprosy, and he believed the same would be accomplished in time in regard to tuberculosis. Very little could be done, however, without special hospitals for tuberculous patients. In Germany, where the greatest advances had been made, much of the money needed had been raised by insurance companies. In our own country the necessary funds would probably have to be raised by taxation. It was well to remember that there were wide differences in the degree of virulence shown by the tubercle bacilli infecting man. Undoubtedly individuals differed widely in their susceptibility to this disease, but some of these bacilli were so virulent that Dr. Vaughn said he did not believe any living human being could successfully resist their invasion in any large number. Statistics could be readily cited to show the absolute necessity of improving the condition of the poor in connection with our efforts to stamp out tuberculosis. He believed that tuberculosis, so long as it remained an unmixed infection, was an entirely curable disease.

The Diagnosis and Treatment of Laryngeal Tuberculosis.—Dr. Jonathan Wright, of Brooklyn, read this first paper in the series on surgical tuberculosis. Regarding the diagnosis of laryngeal tuberculosis he said that he did not feel that laryngoscopy alone, without the history of other symptoms, was sufficient ground for a diagnosis. It was easy to confound syphilis of the larynx with laryngeal tuberculosis, and the worst feature about such an error was that, whereas laryngeal syphilis yielded readily to appropriate treatment, it became almost as fatal as laryngeal tuberculosis if treated as the latter should be. Tuberculous laryngitis was not usually accompanied by dangerous dyspnœa, whereas syphilitic laryngitis was ordinarily associated with shortness of breath. When there was evidence in the larynx pointing to laryngeal tuberculosis, the tuberculous process in the lungs was usually sufficiently far advanced to permit of its ready recognition. If the examination of the sputum in a doubtful case failed to show the presence of tubercle bacilli, the patient should be at once put on antisyphilitic treatment. In laryngeal, as in pulmonary, tuberculosis he was of the opinion that the climatic treatment was the most important factor in the cure of the disease, yet it should be remembered that in a large proportion of these cases the person was so inevitably doomed that it was cruelty to send him away from home. After an exhaustive study of statistics and an extensive clinical experience, he had come to the conclusion that a permanent radical cure of the local lesion in laryngeal phthisis was not effected by any method of surgical treatment. Palliative treatment was an entirely different matter. It was the height of folly and the depth of cruelty to tell a person suffering from laryngeal phthisis that he could not be cured. It was a fact that lactic acid and

probably some other drugs would stimulate torpid granulations to a more healthy appearance, and cause some decrease in the inflammatory swelling, and perhaps occasionally produce an appearance of cicatrization and temporary cure. The local application of iodoform and especially of orthoform in the elegant prescription employed by Dr. Freudenthal relieved the pain, but probably did nothing more. The internal use of opiates was often indicated and justifiable. Detergent sprays gave temporary relief, but produced a favorable psychical impression. The submucous injection of creosote and lactic acid did not appeal to his knowledge of the pathological condition.

Tuberculosis of the Eye; its Differential Diagnosis, Pathology, and Treatment.—Dr. Charles Stedman Bull, of New York, read this paper. He said that our knowledge of tuberculosis of the eye dated back to 1868. Tuberculosis of the eye was chiefly met with between the ages of five and thirty years, and the tendency was to involve the deeper structures primarily.

Eyelids.—In tuberculosis of the eyelids the lesion usually appeared first in the retrotarsal fold. The lids were often much swollen, but were soft to the touch, and often presented distinct folds around the tuberculous mass. It was exceptional to find the tubercle bacilli in sections of the tuberculous mass, yet they might be found in scrapings from the floor of the ulcer. The neighboring lymph glands were not always swollen. Tubercles of the conjunctiva must be differentiated from trachoma, epithelioma, and syphilitic ulceration. In trachoma, the glands were not involved. The differentiation from epithelioma could be made by the age of the patient. The character of the ulceration, the lardaceous aspect of the mucous membrane, and the engorgement of the glands would usually suffice to make the diagnosis. The ulcerative surface should be cauterized unless near the edge of the lid, when it should be excised. If the lesion was primary, the prognosis was good; if secondary it was always unfavorable.

Cornea.—The cornea was much less liable to tuberculous disease than any other tissue of the eye with the exception of the lens.

Iris.—Tuberculosis of the iris occurred most frequently between the ages of five and twenty-five years, and was more frequently secondary than primary. The diffuse form spread rapidly, and occurred in persons predisposed by hereditary tendency to the disease. It occurred in children as small grayish nodules at the ciliary margins of the iris. It might be confounded with gumma, sarcoma, and leprosy. They might be distinguished from the first by their color and by the presence of glandular enlargements, and the usual signs of pulmonary tuberculosis. When the growths were multiple, non-vascular, and gray, and were accompanied by glandular enlargement, they were usually tuberculous. With our present knowledge, enucleation of the eyeball seemed to be the best treatment.

Choroid.—Tuberculosis of the choroid occurred either as solitary tubercle or miliary tubercles. It was most commonly seen before the age of twenty, particularly in little children.

Retina and Optic Nerve.—Tuberculous lesions of the retina and optic nerve were almost always an indication of a tuberculous meningitis. The changes in the optic nerve were always bilateral and consisted in a papillitis and a typical neuritis.

The Pathology, Diagnosis, Special Prophylaxis, and Treatment of Tuberculosis of the Ear.—Dr. Seymour Oppenheimer, of New York, read this paper. He said that tuberculosis of the ear was characterized by the insidious development of a slight discharge without pain. With this there was slight impairment of the hearing, and the drum was of a bluish-white color and somewhat œdematous. To establish the diagnosis microscopical examination of the pus from the deepest parts or even inoculation experiments might be required. Extensive alterations of structure had usually taken place before attention had been called to the possibility of a tuberculous infection of the ear. Prompt and effective treatment of the nose and throat in persons predisposed to tuberculosis was an important prophylactic measure. In such individuals the physician should carefully abstain from the use of the Politzer douche. The local treatment comprised the use of such non-irritating applications as would insure cleanliness. The usual constitutional treatment of tuberculosis should not be neglected.

Acute Tuberculosis of the Mesenteric Lymph Glands.—Prof. Maurice H. Richardson, of Harvard University, made this contribution to the discussion. He said that in general disseminated tuberculosis of the peritoneum it appeared as miliary tubercles, or in masses of greater or less size. In these cases the mesenteric glands might or might not be involved. Sometimes a single group of glands was involved, and this was associated with general disseminated tuberculosis. The symptoms of acute tuberculosis of the mesenteric glands were so obscure that their interpretation was impossible. In chronic tuberculosis of these glands the diagnosis was comparatively clear. In the acute form the symptoms were often those of an ill-defined appendicitis or of a local peritonitis. In addition to the pain and tenderness of the glands themselves there would be tenderness of the surrounding peritoneum. Therefore the diagnosis in the early stages must be mere guesswork. Most of the cases operated upon had advanced to the stage of caseation and of breaking down. The prognosis of acute tuberculosis of the mesenteric glands had always been looked upon as extremely unfavorable, yet he had often seen at operations many examples of spontaneous cure. These cures could not, however, represent the proportion of good results that should be obtained by early surgical intervention. The chief danger was the injury of large veins, thereby compromising the integrity of the bowel. When there was general dissemination, removal of the diseased glands was out of the question. It was not improbable that the removal of some of the larger glands would lead to the disappearance of many others. When the glands were caseous and suppurating, drainage was demanded.

The Surgical Treatment of Urinary and Uro-Genital Tuberculosis.—Dr. Samuel Alexander, of New York, read this paper. He said that while it was possible for the genito-urinary tract to be the seat of ascending infection, clinical observation did not support this view. Primary tuberculous infection of the genito-urinary tract he believed to be generally of hæmic origin. It was probable that the tubercle bacilli entered the genito-urinary tract from the blood, most often through the kidney, although this organ might itself escape at the time. Clinically speaking, the most common seat of primary tuberculosis in this region seemed to be the epididymis. He had found that it was usually associated with more or less involvement of the prostate or of the prostatic urethra. While tuberculosis of the bladder might be primary, clinical data in proof of this were wanting. The object of treatment in so-called primary tuberculosis of the genito-urinary tract should be curative. The removal of isolated tuberculous foci was not in itself curative. Unnecessary and frequent instrumentation was a common and potent exciting cause of the spread of tuberculosis throughout the genito-urinary tract. By a routine examination of the urine for tubercle bacilli many more cases would be diagnosed early. To

succeed in finding the tubercle bacilli in the urine, it was necessary to collect the sediment by the use of the centrifuge. If the urine had stood for some time after having been voided before the examination was made, or if the sediment had been collected by gravity alone, it was probable that the bacilli would not be found.

Kidney.—In all cases of tuberculosis of the kidney in which operation was not absolutely contraindicated by the condition of the patient, surgical intervention was imperatively demanded. As a general rule, the choice should be given to nephrectomy when only one kidney was affected. This operation, he believed, was indicated even in cases in which there was a beginning tuberculosis of the other kidney.

Epididymis.—He was strongly of the opinion that when the epididymis was diseased, excision of the part did as much good as castration. When the epididymis or testicle was to be removed for tuberculosis, as much of the seminal duct should be removed as could be reached.

Prostate.—He was convinced that primary tuberculosis of the prostate was far from infrequent, though difficult to diagnose. It was often possible by rectal pressure to express a few drops of secretion, and in that to find tubercle bacilli when none of these organisms could be found in the urine. As much as possible of the diseased prostate should be removed.

Bladder.—The surgical treatment of tuberculosis of the bladder was necessarily palliative. In the speaker's opinion, local treatment was absolutely valueless.

The Pathology, Diagnosis, Special Prophylaxis, and Treatment of Tuberculosis of the Bones and Joints.—Dr. E. H. Nichols, of Boston, made some remarks on this subject, illustrating them with lantern slides. He said that in the great majority of cases of tuberculous joint disease coming to autopsy, tuberculous lesions were found elsewhere through the body. Very rarely was the joint lesion the only evidence of infection. Primary tuberculosis was so rare that he himself had never seen it. In spinal caries the tuberculous process usually began in the anterior part of the vertebra. The character of the kyphosis depended upon the extent of the process and the region affected. In cases coming to autopsy an abscess was almost always found. Certain extraordinary deviations of the aorta might occur, especially if the disease in the vertebra developed after the person had attained his growth. Mere angular deformity seldom if ever diminished the calibre of the spinal canal sufficiently to make pressure on the cord. Occasionally pressure on the cord was produced by bony fragments. In rare instances an abscess caused a pressure paralysis. In a very large proportion of the cases of hip-joint disease the process began in the acetabulum itself, and hence, in such cases, excision of the head of the femur did not remove the primary focus. In the ankle joint the primary focus might be in the lower end of the tibia or in any of the tarsal bones.

The Pathology, Diagnosis, Special Prophylaxis, and Treatment of Tuberculosis of the Skin and Superficial Fascia.—Dr. John A. Fordyce, of New York, also gave a lantern exhibition in addition to discussing this subject. Speaking of lupus, he said that it might remain as a single patch for many years. The recurrence of lupus nodules in scar tissue spontaneously formed or following operation was common. Scarification of a lupus patch was sometimes followed by redness and phenomena similar to those observed after the injection of tuberculin. Secondary infection with pus organisms might give rise to considerable crusting, thus obscuring the true nature of the lesion. Epithelioma occurred so frequently as a complication as to indicate something more than a merely accidental relation. Age was a predisposing factor in lupus. The greatest difference of opinion prevailed concerning the probability of the tuberculous process spreading from the lupus patch throughout the body, and while many observers maintained that it was a common result, others declared that in an extensive experience they had not seen the two associated. Late syphilis and epithelioma had a tendency like lupus to clear up in the centre and spread at the periphery. When epithelioma developed on a lupous surface the diagnosis was rather complicated. Blastomycetic dermatitis had been confounded with cutaneous tuberculosis. Tuberculosis around the orifices was usually preceded by marked tuberculosis of the lungs.

Fourth Day—Thursday, October 18th.

The Treatment of Ichthyosis Hystrix by Electric Light.—Dr. George W. Goler, of Rochester, presented a brief report on this subject. The patient was a boy of nine years who had developed ichthyosis at the age of four years. When seen in July, 1900, the affection involved both the upper and the lower extremities. The first treatment was made upon the arm, the area selected being well rubbed with lanolin and then a light from a twenty-millampere lamp was projected through two eight-inch plano-convex lenses upon the arm. This was kept up for twenty minutes, and was repeated on the following day. On the third day the skin had lost its warty character, and at the end of six or seven days had assumed its normal appearance. The other affected portions of skin were treated in a similar manner, and at the end of twenty days, and after eighteen exposures of half an hour each to the electric light, the disease had entirely disappeared. It had not returned since, and the patient now perspired naturally over the area of skin formerly affected.

The Differential Diagnosis of Ectopic Gestation with Special Reference to Early Abortion.—Dr. Hiram N. Vineberg, of New York, read this paper. He said that he was not one of those who thought the differential diagnosis of this condition always easy, and that it could be made by relying solely on one or two prominent symptoms. He had followed the plan of making an exploratory incision into Douglas' culde-sac in a number of doubtful cases, and looked upon this as an important diagnostic aid. If an ectopic pregnancy was found, unless the conditions were specially favorable the operation was completed through a suprapubic incision. Every case of early uterine abortion should be looked upon with suspicion, and when there was much doubt the patient should be anæsthetized. The flow attendant upon a ruptured ectopic pregnancy was apt to occur as a mere "show," appearing and disappearing at intervals. The pain usually experienced was described as like that of labor. Microscopical examination of pieces of membrane discharged may show decidual cells, but even the most expert microscopist could not distinguish between the decidual cells of a uterine and of a tubal pregnancy. An erroneous diagnosis was apt to be made in cases of irregular sacculation of a pregnant uterus, elongation of the cervix, and retroflexion of the uterus.

Dr. Frederick Holme Wiggin related a case in which he would have been misled by a retroflexed uterus if the woman's appearance had not denoted something more serious, thus leading to examination with the uterine sound.

Drs. C. C. Frederick and E. V. Delphey also narrated interesting cases in point.

The Resources of Modern Minor Gynæcology.—Dr. A. H. Goelet, of New York, read a paper with this title. In it he called attention to a rubber sheath which he had had made for laminaria tents, thus per-

mitting of the use of this excellent means of securing uterine dilatation without fear of causing infection. Concerning the topical use of glycerin in gynæcology, he said that strips of gauze moistened with glycerin would be found far better and more comfortable than the usual cotton tampons. He had found a mixture of one part iodine and thirty-two parts glycerin more useful than boroglyceride. He considered uterine irrigation a very important therapeutic resource. He had devised a special form of double metallic irrigating-tube, which could usually be passed in without previous dilatation. If, however, it met with obstruction, it could be withdrawn and a rubber tube slipped over it to give the necessary insulation, and then it could be connected with the negative pole of a galvanic battery until the desired patulousness of the os had been secured. Regarding electricity, he said that despite the fact that surgical gynæcologists had repeatedly endeavored to kill electrical treatment in gynæcology, it was still very much alive, and was doing much good. It was a most valuable gynæcological resource. Galvanism would relax the cervical canal and promote drainage, and so materially aid the treatment of endometritis. It would dispel pelvic congestion and relieve pain dependent upon pelvic exudates much better than any other agent except faradization. He had found a few internal remedies useful in gynæcological cases. The combination of bromide and iodide of potassium was particularly valuable in cases of pelvic pain from the presence of exudates. Bromide of arsenic would often lessen the menstrual flow even in cases in which curettage was indicated.

Dr. Eden V. Delphey, of New York, said that he had used the rubber-coated laminaria tents with much satisfaction. Faradization had proved in his hands a most useful means of relieving pelvic pain and also in treating functional amenorrhœa.

Strabismus and its Management.—Dr. Julius H. Woodward, of New York, presented this paper. In it he described both the paralytic and the non-paralytic forms of strabismus. The symptoms of the former, he said, were confusion of sight, vertigo, double vision, impairment of the sense of perspective, deviation of one of the lines of sight from the object observed, and a confused feeling in the head. The diplopia was the most characteristic and troublesome of the symptoms. The first symptom of non-paralytic strabismus was deviation of the line of sight of the squinting eye away from the object on which the gaze was fixed. If the defect was promptly corrected a considerable degree of vision might be restored. In these cases the patient did not complain of diplopia, for even when it was present the person was not conscious of it. The deformity associated with squint had an important influence upon the temperament of the individual, and this sociological aspect should be kept steadily in mind. In the majority of cases more than one operation would be required. It was frequently advisable to begin the operative work at an early age.

Investigations upon Specific Corporal Gravity and upon the Value of this Factor in Physical Diagnosis.—Dr. Heinrich Stern, of New York, read this paper. He said that it was the density of the tissues and not the absolute weight of the body that was an important factor in physical diagnosis and in life insurance. In his investigation of this subject he had determined the specific gravity of the body by dividing the amount of its absolute weight by the loss of weight sustained when it was submerged in water. He had at first made use of a huge hydrostatic balance for determining the specific gravity, but further study had shown this to be unnecessary, as the result varied but slightly if the body was submerged instead of suspended. Fat had an average specific gravity of 0.0932. The larger proportion of fat in the female naturally made the specific gravity of the average female less than that of the male. The specific gravity of children was less than that of adults, but did not differ materially in the two sexes. The body weight of the aged was above the average for middle life. The specific gravity in the latter in the male was between 1.057 and 1.063, and in the female between 1.051 and 1.061. His studies also showed the relation between the body density and the density of the blood throughout the different periods of life to be so close that it was perfectly feasible to estimate the specific gravity of the body by determining the specific gravity of a drop of blood from the person. The determination of corporal specific gravity would show: (1) Body soundness, (2) body immunity, (3) endurance, and (4) the probable duration of life.

Aseptic Minor Surgery.—Dr. Douglas Ayres, of Fort Plain, gave in this paper a few thoughts on the pre-aseptic period, the thoughts and provings that had gradually led up to the present greatly improved technique, and the arrangement of an office or house by which modern surgical methods could be best carried out.

Amputation at the Hip Joint. A Report of Two Hundred Cases in which the Author's Method of Hæmostasis was Employed.—Dr. John A. Wyeth, of New York, read a paper with this title in which he gave a review of the literature. He said that the first hip-joint amputation by his method had been done in February, 1890. The operation had been done without the two pins in some instances, but since these pins, if properly inserted, were not in the way, and the control of hemorrhage was better, they should be used invariably. A wick of sterilized gauze was inserted into the cavity of the acetabulum because of the free oozing from the muscles. Two other successful methods had been used by surgeons in recent years. One of these was the performance of abdominal section and the control of hemorrhage by digital compression of the aorta. The other, devised by Dr. W. L. Estes, consisted in making a gradual dissection of the tissues, exposing the femoral vessels, and ligating them before their division. The method by laparotomy was objectionable because of the unnecessary entrance of the peritoneal cavity. Compression of the common iliac could not so completely control the hemorrhage as the pins and elastic ligature, because of the free anastomosis of branches of the opposite iliac within the pelvis and on the abdominal wall. In the two hundred and forty-seven cases of disarticulation of the hip that he had collected in this report, the total mortality had been fifty-two, or twenty-one per cent., though this included cases of death from intercurrent disease.

Drs. J. A. Bodine, H. Lilienthal, and W. B. Coley presented reports showing clearly that in their experience the Wyeth method was the best of all.

Report of Three Cases of Intestinal Obstruction due to Meckel's Diverticula.—Dr. John F. Erdmann, of New York, made this report (see page 645).

Intraspinal Cocainization for the Production of Surgical Anæsthesia.—Dr. S. Ormond Goldan, of New York, read this paper. He said that while he did not believe this new method of anæsthesia would supersede the other and better known ones, he felt sure that it would be held as a reserve in special cases. It was generally admitted that the credit of devising this striking method of anæsthesia should be given to Dr. J. Leonard Corning, of New York City, who had published in 1885 a series of interesting papers detailing his experiments in this field. The finest needle through which the cerebro-spinal fluid would pass should be selected. The ordinary long aspirating needles had too large a calibre. He had had constructed special needles made in one piece of four-

teen karat gold. These could be kept sharp by the physician. A sterilized and freshly prepared two-per-cent. solution of cocaine should be used. The needle should be introduced very quickly through the skin, and then very slowly until cerebro-spinal fluid began to drop from the needle. After the cocaine was injected, the syringe should not be removed from the needle for at least two minutes. In a period varying from four to twelve minutes the anæsthesia would be sufficiently complete for operation. In no case had he failed to get the cerebro-spinal fluid, and he had invariably followed most carefully the prescribed technique. The first two cases had been failures, probably because such large needles had been used as to permit the solution to flow out into the tissues external to the canal on their withdrawal. In these cases the cocaine solution had been tested and proved active. The usual quantity of cocaine injected was ℥j xx. of a two-per-cent. solution, and this dose should not be exceeded until it had been proved to have exerted no effect; then a second injection might be given. Beginning anæsthesia was indicated by the patient experiencing a feeling of numbness in the limbs. It was his present practice to give whiskey in every case before performing spinal puncture.

Dr. M. L. Maduro, of New York, said that he had seen complete collapse, and had heard of other complications following this method. He felt sure that, at the present time, few physicians would be willing to submit to this method themselves.

Dr. Bodine thought some of the uncertainties of the method might arise from a too rapid diffusion of the cocaine solution, and suggested that this might be obviated by adding salt solution to the fluid injected, thus increasing its density. Skin infection could be best guarded against by making an incision through the skin before introducing the needle.

Dr. R. H. M. Dawbarn remarked that he had known of this method of anæsthesia having been already tried in a case in which it was required to open a large boil on the thigh. It was not improbable that the cord might be so injured as to lead ultimately to secondary neuroses.

The Technique of Bloodless Work.—Dr. Robert H. M. Dawbarn, of New York, read a paper with this title. He said that the older the surgeon, the greater his respect for loss of blood. Operations on the extremities shoul be made bloodless. The best method was to raise the limb and for several minutes "milk" the blood out of the part. A rubber tube, half an inch in diameter, should be passed around the limb two or three times and fastened with a piece of wet bandage. For the control of medical hemorrhage, especially from the lungs, the most useful procedure was tying a cord around three of the extremities so tightly as to cause the limb to swell. This was kept up until the patient felt faint from the cerebral anæmia produced, and broke out in a cold sweat. After the first limb had been bandaged in this way for a short time, it should be released and the fourth extremity bandaged, and this process should be repeated with each limb in turn. After two or three hours the original hemorrhage should have been sufficiently controlled.

Operative Treatment of Symblepharon by the Use of Thiersch Grafts.—Dr. Wilbur B. Marple, of New York, presented a communication on this subject, in which he advocated his original method of using a shell of glass to hold the graft in position until union had taken place. The graft was stretched over the glass shell, and the latter was left in from three to seven days. If the patient experienced pain after the operation it usually meant that the shell was pressing on the cornea. The graft must be one-half to one-third larger than the defect to be covered, as it would be considerably reduced by contraction at the time, and, to a lesser extent, subsequently. The objection to the use of grafts from the conjunctiva and the mucous membrane of the mouth was that these did not sufficiently resist this subsequent contraction.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 18, 1900.

William H. Thomson, M.D., President.

The discussion of the evening was a continuation of that begun at the last stated meeting.

Advantages and Limitations of Sterilizing and Pasteurizing Milk.—Dr. A. D. Blackader, of Montreal, read this paper. He said that milk obtained under unfavorable conditions and kept at a rather high temperature contained many bacteria, and in addition, their spores and toxins. According to our present knowledge, all forms of bacteria were undesirable in an infant's food. It had been shown that 99.8 per cent. of the bacteria could be destroyed by pasteurization. The older the milk was the more difficult it was to pasteurize it. Pasteurization at 70° C. destroyed the vast majority of the forms liable to produce extensive and rapid change in the quality of the milk. It was necessary in most instances to maintain the pasteurized milk at a low temperature in order to preserve it from further change. However, the same could be said of milk heated to 100° C. Milk exposed to 60° C. or 140° F. had ninety-six to ninety-nine per cent. of its bacteria destroyed. Russell had found that when milk was heated in tubes to 140° F. tubercle bacilli were not entirely killed because the little pellicle which formed on the surface of the milk protected the bacilli to some extent. If this pellicle was broken up complete destruction of the tubercle bacilli was assured. Milk raised to 100° C. was markedly altered in taste, smell, and chemical composition. The albumin and globulin were coagulated, the lecithin and nuclein were destroyed, and the organic phosphates converted to some extent into the inorganic phosphates. For the coagulation of milk in the stomach calcium must be present in a more or less free form. It was probable that the preliminary curdling of milk was an aid to digestion. It was also probable that in milk heated in this way certain useful ferments were destroyed. As long as milk could be rendered practically sterile at comparatively low temperatures it seemed useless and even deleterious to subject the milk to a higher temperature. It was generally stated that milk was pasteurized at 157° F.

Relation of Scurvy to Recent Methods of Artificial Feeding.—Dr. J. P. Crozer Griffith, of Philadelphia, discussed this topic. He said that two years ago the American Pediatric Society had published the collective investigation on scurvy in this country. There were three hundred and seventy-nine cases reported, and in three hundred and fifty-six the nature of the diet at the time of the development of the disease was stated. Food containing or derived from starch seemed to be a powerful etiological factor. The use of cooked or partially cooked milk seemed to be a cause of scurvy in about nineteen per cent. of the infants. Several children developed the disease on a diet of raw milk. The speaker also referred to sixteen of his own cases which showed very plainly the very large proportion of cases in which some proprietary food appeared to be the cause. It was evident also that scurvy developed even when the milk used had been taken raw, or only very slightly heated. One fact that had impressed itself specially upon his mind was, that irrespective of the food much depended upon individual peculiarities.

The Use of Cereals, Emulsions, and Proteids.—Dr. T. M. Rotch, of Boston, read this paper. He said that cereals were added either to increase the nutritive value, or to aid the digestion of the proteids by acting mechanically on the coagulum. The addition of an element such as starch, that never existed in milk except as a foreign element, seemed to him utterly irrational. Barley water was the favorite cereal diluent for milk, although actual experiment showed that there was no difference in the various cereal diluents, provided they were of the same degree of dilution. These statements had received abundant confirmation in some recent experiments conducted by Drs. White and Ladd, of Boston, under his directions. They had been unable to show any marked difference between the laboratory milk and that in which the natural emulsion had been disturbed by the use of the centrifuge. It was true that at times globules of fat would be found on the surface of the milk, but investigation seemed to show that this occurred only in warm weather, and not then unless the milk had been disturbed by transportation for a considerable distance. In his clinical experience he had been unable to find any special difference in the action of such milk and milk that did not exhibit this separation of the fat. Recent experiments seemed to indicate that whey was a better diluent than barley water, and that milk so diluted was less likely to show disturbance of the emulsion.

General Principles of Artificial Feeding, and the Home Modification of Milk.—Dr. L. Emmett Holt read a paper with this title. He said that good breast milk must be looked upon as the ideal food; the nearest approach to it was fresh cow's milk. Though the latter contained all of the elements needed, they were present in improper proportions, and the elements themselves were not identical in composition with those of breast milk. It was for this reason that cow's milk could not be fed to most infants without some modification. Percentage feeding was a great step in advance, but while the formulas succeeded well with some children, they utterly failed with others. Experience had shown that no single formula could be made to do duty generally. The physician must know the approximate quality of the milk used at the home. The formulas actually needed might be grouped into three series: (1) Those in which the fat was three times the proteids, or the ratio in breast milk; (2) those in which the fats were twice the proteids, and (3) those in which the two were nearly equal. As a rule, the first formula was suited for normal cases up to the third month; the second was suited for them from the third to the tenth month, and the third from the tenth to the thirteenth month. Ordinary milk after standing four hours contained in its upper third about all of the cream. A simple plan was to strain into a jar that which was needed for each day, and then to place the jar in a vessel containing ice. The first formula called for the proportion of 3 to 1, or ten per cent. fat, and was obtained by taking one-third of the upper milk. The second formula was represented by half of the milk, or seven per cent. fat.

Dr. Joseph E. Winters said that the physician could not help to be impressed with the fact that infants suckled by a healthy mother were rarely sick, and that while eight per cent. died, fifty-one per cent. of artificially fed infants died. These were the figures from private practice, whereas in the Charity Hospital at Berlin, where the infants were for the most part artificially fed, the mortality varied between fifty-nine and ninety-three per cent. As a result of experience with laboratory feeding he had come to feed new-born infants from the very first day of life, and had found that this practice prevented the loss of weight generally seen in the first week of life. The formula which he found most generally useful in the newly born was, fat 2, sugar 7, and proteids 0.25 per cent. If the infant was premature he increased the sugar to even ten per cent. Cow's milk for infant feeding should contain nothing which was not found in human milk, and it must be pure and fresh. He believed that when one reaches 0.50 per cent. proteids all infants would do better on three per cent. than one one per cent. fat. When one reaches one per cent. proteids there should be the percentage of fat found in human milk—four per cent. It was very important to increase the proteids as rapidly as possible, but it was necessary to do this much more slowly in summer than in winter. In the cool months an infant should be on two per cent. proteids when about four months old. During all the years that he had been using laboratory milk, and with unvarying success, a cereal had not entered into one of his prescriptions. Hundreds of infants had been brought up to full milk on laboratory milk and without any disturbance whatever. For the past three years he had been using the laboratory milk absolutely raw, and the infants had done better than before. There had been less complaints of sourness and signs of fermentation since he had been using raw milk than before with the pasteurized milk. In one instance, some raw milk and some heated milk had been sent on board a steamer. The heated milk had soured first. He had made a trial of gravity cream at one time, and had not found it superior to the centrifugal cream for infant feeding. When milk was immediately cooled to 40° F. after milking, and was kept at that temperature, it would keep sweet a long time. Proper supervision was more of a safeguard than pasteurization.

Dr. H. D. Chapin said that the great defect of percentage feeding was that it took no cognizance of the differences in composition of cow's milk and breast milk. This, he thought, disposed of the argument that the addition of cereals was the addition of a foreign body. Any trouble from the starch could be easily overcome by dextrinizing the gruel, and the mechanical separation of the particles of coagulum made a milk diluted in this way much more digestible than milk diluted to the same extent with water alone.

Dr. R. G. Freeman commented upon the great differences of opinion regarding the effect of heating milk. Some used pasteurization at 155°, others at 167° F., and one physician in this city heated the milk to 190° F. We had been told that breast-fed infants were rarely ill, yet this could not be because the milk was sterile, as the fissured and dirty nipples usually afforded a good opportunity for the introduction of germs. The breast-fed infant got a fresh raw milk containing a few bacteria. Most of the milk received in this city was twenty-four hours old when it was received, and was twenty-four hours older when the baby was through with the day's supply. The long transportation and the opportunities for contamination with pathogenic germs added to the risks of such milk; hence it seemed wise to heat milk. Pasteurization at 155° F. for twenty minutes had practically no effect on the composition of the milk, yet the milk was rendered almost sterile—at any rate the common pathogenic germs were killed.

Dr. Louis Fischer said that as scurvy was known to be produced by feeding heated milk, and that improvement rapidly followed change to raw milk, it seemed reasonable to begin feeding with raw milk. A healthy child should gain six or eight ounces a week. His experience had been that children fed on laboratory milk exclusively were backward in development. Children using this milk were anæmic and their skin was flabby even though they were the children of the wealthy. The theory of percentage feeding had always appealed to him, yet he had never been able successfully to put it in practice. Dr. Jacobi had often

called attention to the frequent fluctuations observed in the composition of mother's milk, and this in itself must throw considerable doubt on the practical value of percentage feeding.

Dr. A. M. Spalding said he had had a good deal of experience with infant feeding and with the modification of milk, and had had good success with the use of raw milk modified so as to make it approach the composition of mother's milk. Milk could be modified so as to adopt it nicely to the wants of the individual. He saw no reason for the addition of cereals.

Dr. Rotch said, in closing, that he had seen very large tough curds vomited by breast-fed infants, but the density of the coagulum was dependent upon the proportion of caseinogen present. By reducing the proportion of caseinogen the coagulum would not be so tough.

Dr. Chapin remarked that under the ordinary conditions of practice it was necessary to split up the curd by some diluent such as the cereals.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 20, 1900:

	Cases.	Deaths.
Tuberculosis	254	166
Typhoid fever	88	16
Scarlet fever	55	1
Measles	36	1
Diphtheria	192	35
Laryngeal diphtheria (croup)	4	3
Cerebro-spinal meningitis	0	0

Leprosy in China.—Dr. Wittenberg, writing on the above subject, states that the pure nerve form is the least common. In such cases, as is well known, the patients may go on for years. As to the mixed form, it is fairly common, but it is a difficult matter to estimate the number of lepers in any given district. The sufferers lead the common life so long as they remain free from destructive lesions. When these occur to any marked degree, the leper is either segregated in a hut or he is allowed to wander about the country sustaining life by begging. At other times the relatives get rid of him by burying him alive, a proceeding to which the patient readily consents. He is given a good meal as a farewell banquet, possibly joins in the funeral procession, following his own coffin, and after partaking of a generous dose of laudanum, philosophically settles down comfortably in his grave. This is Dr. Wittenberg's account, and as it accords with the fatalism of the Chinese there need be no hesitation in accepting it as accurate. The German observer also records cases of direct contagion—for instance, from mother-in-law to daughter-in-law, but no further details in this connection are given.—*British Medical Journal.*

Antivenene.—For some years past Professor Frazer of Edinburgh, and Dr. A. Calmette of the Pasteur Institute, Lille, and others have been engaged in the very laudable endeavor to discover a remedy for snake-bite. This, they believe, has been found in the poison of the reptile itself. The system adopted by the doctors is that of Pasteur, the scope of which since its first inception has become so widely extended as to embrace many diseases formerly regarded as incurable, but now found to be more or less amenable to the new treatment which consists of inoculation with attenuated virus of the disease itself, or with the blood serum of animals which have been immunized by the process, the treatment being employed not only as a cure but as a prophylactic. In the case of snake-bite the remedy consists in the subcutaneous injection of gradually increasing doses of the venom of deadly snakes until the animal treated becomes proof against the poison. The blood serum of an animal thus immunized, known as antivenene, or of the snake itself, is used to cure and protect others. The animals thus treated have been chiefly rabbits, rats, and pigeons, and it is asserted that instead of being injured or weakened by the experiments, they gain in weight and vigor. The doses administered have been proportioned to the weight of the animal, and four methods of administration have been tried experimentally. In the first the venom and the antivenene were mixed together before injection. In the second the two were administered separately but simultaneously, in the third and fourth the antivenene was injected before and after the venom. The latter is of course the only method applicable to actual cases of snake-bite, and it is of special interest to know how long after the bite antivenene may be relied on as a remedy, because the poison of the more deadly of the snakes acts so quickly that no remedy can avail unless close at hand. In some of Dr. Calmette's experiments serum injected an hour and even an hour and a half after a large dose of venom seems to have effected a cure, which would at all events allow time for the application of the remedy should any one competent to administer it be near at hand.

Alcohol in Illness.—Professor Atwater, writing in *Harper's Magazine* upon the much vexed subject of the use or uselessness of alcohol, says: "In talking with physicians about this matter I have been much impressed by the frequent and emphatic statements of their experience in administering alcohol to patients in forms of disease when the bodily activities are at a low ebb. They tell me that they often find that people in such a condition will take without intoxicating effects quantities of alcohol which would under ordinary circumstances produce drunkenness. They say, furthermore, that there are many cases in which the bodily functions are maintained, and life is even saved by alcohol when ordinary food could not be endured. From the standpoint of the physiological chemist this effect of alcohol would seem entirely natural. The bodily functions are weakened and the power of digestion is impaired. While the patient is lying still the labor required of the muscles is not large and the chief need is fuel to carry the body through the time of stress. What is wanted is a material which will not have to be digested, can be easily absorbed, is readily oxidized, and will supply the requisite energy. I know of no other material which would seem to meet these requirements so naturally and so fully as alcohol. It does not require digestion, is absorbed by the stomach and presumably by the intestine with great ease. Outside of the body it is oxidized very readily, within the body it appears to be quickly burned. Why it should have less effect upon the nervous system in some forms of illness than in health is perhaps hard to say, but that it should under these circumstances be an invaluable source of energy is easy to believe."

Drug-Store Physicians.—The latest development of the cheap medical-treatment scheme is a combination of society and druggist. The prospectus of one of these relief bureaus states that for "$1 admission fee and 50 cents monthly dues a family may secure the reduced rates offered by the bureau. The rates are 50 cents a call and 25 cents for a consultation and special rates for chronic cases." The prescriptions are all turned over to the drug stores in the combination, and as one of the subscribers said, "When you

pay for the medicine you begin to realize that you have not got a bargain." A physician who practises his profession in the crowded East Side district, where many of the cheap medical-treatment schemes have flourished, said, "The laws which make a certificate from the Board of Regents' examiners necessary to practise medicine have done much to drive the quacks out and to make the drug-sellers stick to their business, but these clubs and bureaus still keep at it with the help of regular physicians. But the service is unsatisfactory because the physician who is employed by another person to attend to your family, or the physician who gives bargain-counter service, never becomes the friend of the family and is soon dropped for a regular practitioner. The family gladly pay a little more for the satisfaction of speaking about 'our doctor,' a distinction which raises them a degree above their neighbors who employ a club physician or go to the drug store when the bureau doctor may be seen there."

Sale of Patent Medicines in Great Britain.—The stamp duty paid on medicines during the year ended March 31, 1900, amounted to the sum of £288,827, being an increase over the previous year of £22,423. There has been a steady increase in the net receipts since 1894 when the amount was £213,210, the lowest during the past ten years.

The Census.—The *Review of Reviews* for October is rather sceptical as to the large increase of population in this country estimated by some computators, and says, "Is it true then that there has been any appreciable increase during the present decade in birth rate or, on the other hand, any marked decrease in the death rate, which would favorably affect the average annual increase of our total numbers? Doubtless the continued improvement of sanitary conditions in large towns and the general progress in the conditions of living and in the treatment of disease are adding steadily, if not rapidly, to the average longevity of our people. But all indications would tend to confirm the impression that the average annual birth rate is declining rather than gaining in the United States. In France, for example, although the modern improvements in sanitation, treatment of disease, and care of children are diminishing the death rate, there has at the same time been such a falling off in the birth rate that the total population figures are approximately maintained solely by reason of a moderate stream of immigration from Italy and other neighboring countries. It is perhaps true that there are now some localities of considerable extent in the United States, where, if it were not for the fact that there is some immigration, and also that there is a comparatively high birth rate among the immigrants, the total population would by no means hold its own on account of the lower birth rate among the native American element. An analytical study of the facts that the new census will gather must throw much light upon interesting questions touching the present tendencies of population in this country. If the statistics are to be relied upon the increase in population that was due to the excess of births over deaths was about fourteen per cent. for the ten years 1880 90, but, further, assuming the correctness of the immigration statistics for the past decade, if we accept the estimates which call for a population of 80,000,000 this year we shall have to look to the excess of births over deaths for a gain of almost twenty-two per cent. To any one at all familiar with vital statistics it is evident without further discussion that such a radical change in the conditions of population increase in the United States could not possibly have taken place. Even if one were to be content with estimating that we should have gained population at the same average rate in the current decade as in the one preceding it would still be necessary on account of the falling off in immigration to rely upon a considerably higher rate of gain in the excess of births over deaths in order to bring up the total. And there is not sufficient reason to believe that the actual census work will show any such gain."

Medical Commission in South Africa.—It is asserted, and to those able to read between the lines it would appear with some degree of truth, that those gentlemen who have reflected most severely upon the conduct of medical and surgical departments of the British army in South Africa are not so much swayed by motives of humanity or even by the sentiment of patriotism but by the less unselfish aim of the advancement of themselves politically and for the desire of notoriety. Most of those who peregrinated through South Africa in search of information were members of Parliament, who, aware that a general election was at hand, judged that the showing up of abuses of the war would be an excellent battle cry with which to rouse the passions and gain the votes of their constituents. Among this band is numbered Mr. Murray Guthrie, M.P., who, not content with airing his opinions as a witness before the commission, contributes a poorly constructed article to the *Nineteenth Century* of September, in which he, without fear of contradiction, ventilates his views at length. He criticises in a severe and palpably unfair manner the whole working of the British army medical corps and ends by saying, "It can scarcely be questioned that the government and Lord Roberts did everything in their power to meet and even foresee the difficulties that occurred, fulfilling every demand that was made upon them in the most generous spirit and even giving more than they were asked for. I am therefore compelled to urge that the deficiency of doctors and orderlies and nursing sisters was due to a lack of foresight, and that the blame rests on the head of the medical department in South Africa. This being so one is reluctantly brought to the conclusion that the local military authorities were unfitted for the task they had to perform, a task I admit of the greatest difficulty and magnitude and one which I do not think their previous training in any way fitted them to cope with. There was apparent at headquarters, where most of the sickness prevailed, an obvious lack of energy; initiative was non-existent. Had the Royal Army Medical Corps had at headquarters some men of capacity and determination who would have grasped the whole problem and worked it out in time I believe there would have been no occasion for a royal commission."

Consumption of Spirituous Beverages.—H. Bence-Jones, in a paper read before the British Statistical Society, gave the following figures with regard to the above-named subject: The amount of wine that is drunk per head in wine-consuming countries is amazing. In France the consumption per capita is twenty-four gallons a year, while the average Italian drinks twenty gallons annually, and the average Spaniard eighteen. But in mere quantity the beer-drinkers far exceed the wine-drinkers. Thus the annual consumption of the United Kingdom is nearly thirty-two gallons a head; that of Germany is twenty-seven gallons; that of the United States where the Saxon element predominates, is thirteen gallons. The general impression is that Germany heads the list, but this is true only of parts of the Empire. Bavaria leads the world in the consumption of beer, its inhabitants drinking at the rate of fifty-six gallons a head a year. Wurtemberg makes a good second with forty-three gallons a year, while each inhabitant of the Grand Duchy of Baden may be reckoned as drinking thirty-six gallons in a year. But this indulgence is balanced by a very

moderate rate of indulgence in other parts. Taken as a whole, Belgium leads the world in the matter of beer-drinking. In fact, Beligum seems to be a self-indulgent little country, for in addition to this large amount of beer its inhabitants drink per capita twice as much wine and spirits as the English do. Belgium drinks more of alcohol in every form than any other nation (of which statistics are to be had), with the possible exception of Denmark. Denmark is not so much of a beer-drinking country, though its twenty gallons a head annually is a pretty large average; but it has the pre-eminence, affix to it what adjective you like, of drinking more spirits than any other nation—no less than three gallons per head. No other nation consumes more than two gallons per head. The countries which take even so much are France, Germany, Austria, Holland, Belgium, and Sweden. In the United Kingdom, the Russian Empire, the United States, and Switzerland, the average consumption is about a gallon per inhabitant. Of all Great Britain's colonies Canada holds the proud position of being the most sober, indeed it is probably the most abstemious country in the world. The consumption of spirits, too, is steadily decreasing. In 1898 the consumption of spirits was only a little more than half a gallon per head, while of wine there is not consumed more than one-tenth of a gallon per capita. Three and a half gallons of beer are drunk per capita annually. Coffee is being consumed more and more both in Canada and in this country. The consumption of coffee, indeed, in the United States exceeds that of any country in the world. The Americans drink anually eleven pounds of coffee a head, the Germans five, and the French three and a half a head.

Tuberculosis in the Russian Army.—Dr. H. K. Chtchepotiev published last February in *Vratch* the sick rate from tuberculosis in the Russian army during the octennium 1890–97. During that period it is said to have amounted to 4 per 1,000 annually, and the death rate to 1.07 per 1,000. Contrasting these high rates with the condition of things prevailing in other countries, the author finds that the annual admission rates of tuberculosis in the German army is 2.3 per 1,000 of strength, in the Austrian army 3.4 per 1,000, in the French army 5.0 per 1,000, the death rate varying from one-sixth to one-third of the total mortality from all causes. In the French army, according to Makiewicz, out of 1,000 soldiers invalided for tuberculosis 116 had acquired the disease before enlistment, while 197 developed tuberculous symptoms during the first six months of their service and 278 during the second six months. In the course of their second year 254 were found to be affected, leaving only 155 who remained immune until they had served two years and upward. At Kiev Dr. Chtchepotiev found that during the period from January, 1895, to November, 1899, the number of admissions to the military hospital on account of tuberculosis was 527. Of these 111 men had less than six months' service, and 32 less than a year's. The second year furnished 127 tuberculous cases, the third 111, the fourth 95, the fifth 33, sixth and upward 18; 12 of the young soldiers in the first series died in hospital, the remaining 99 being sent to their homes while still able to travel. Dr. Chtchepotiev is strongly of opinion that the great prevalence of tuberculosis in the Russian army is due to entry each year of a number of recruits who carry in their systems seeds of the disorder. Although a great many of the affected soldiers have tuberculous antecedents, hereditary or otherwise, it is also true that of the men attacked after serving a year or more fully half are strong and robust with nothing about them to suggest predisposition or inheritance of family taint. Unfortunately, it is not always an easy matter to recognize incipient phthisis pulmonalis. A recruit who presents easily diagnosed symptoms of tuberculosis can, to a certain extent, be guarded against, but the harborer of latent germs is a veritable anguis in herba. Living as soldiers do more or less promiscuously, sleeping in numerously occupied dormitories where they must inevitably respire air that has already passed through human lungs, it is of the utmost importance that every one of these should be as sound as possible. In order completely to eradicate tuberculosis from the army the most strict inquiry into the previous medical history of every recruit should be insisted on and provided for, together with a far more searching examination of his physical condition than at present obtains. The small additional cost thus entailed would be recouped over and over again, even though but one-quarter of the present loss of efficiency from a preventable cause were to be attained. As a palliative it would be well to provide for the early elimination of tuberculous patients. At present the custom in the Russian army is to retain them as long as they can manage to carry out their duties. Incidentally Dr. Chtchepotiev confirms the fact already noticed by several writers that Jewish soldiers are seldom the victims of tuberculosis.—*Lancet.*

Diagnosis of Tuberculosis of the Kidney.—1. The frequent micturition. 2. Limpid polyuria. 3. Pyuria, spontaneous and persistent. 4. Hæmaturia, slight, and repeated capriciously. 5. Renal tumor.

In young, pale, somewhat feeble subjects we have practically three types: 1. Patient has hæmaturia alone. 2. Patient has hæmaturia and pyuria. 3. Patient has tumor alone.

1. Hæmaturia. The peculiarities of hæmaturia due to renal tuberculosis must be borne in mind. In tumor, much more abundant. In stone, due to exercise and controlled by rest in bed. Frequent micturition, pyuria, albuminuria, and tuberculosis elsewhere, either in genito-urinary tract or any place else in body, make the diagnosis possible.

2. Patient has pyuria and hæmaturia; this usually follows the hæmaturia and the limpid polyuria. The characteristics of the pyuria are those of pyelo-nephritis. To determine that it is tuberculosis: (*a*) Presence of bacilli tuberculosis; (*b*) presence of tuberculous foci elsewhere, especially of bladder around the opening of the ureter; (*c*) general condition; (*d*) absence of antecedent infection.

3. When tumor alone exists, then the diagnosis is alone possible when other foci are to be found, or when the bacilli tuberculosis can be demonstrated in urine or in fluid obtained by puncture.—C. S. Evans, *Cincinnati Lancet-Clinic.*

Food Poisoning by Copper a Fallacy.—The poisonous nature of copper salts is held by Dr. T. W. Hime, medical officer of health of Bradford, England, to afford insufficient ground for the prohibition of the sale of coppered vegetables, and he asserts that there is no more reason for such prohibition than for interfering with the sale of the innumerable kinds of fruits, vegetables, shell-fish, cereals, mineral waters, wines, and animal flesh which naturally contain the metal in some form. These views were advanced in a paper read before the British Association, wherein Dr. Hime urged that if any general prohibition of the sale of foodstuffs containing copper were attempted absolute and general starvation would be the inevitable result. so widely is the natural presence of copper in articles of food extended. But *The Lancet* thinks that on such grounds Dr. Hime might justify arsenic as a useful food preservative, since it is now known to be a normal constituent of the body though in infinitesimal amount. Objection, however, is taken, not to the plan of preserving the color of peas by copper, but to the consumer not being made plainly aware

that such is the case with the provisions he consumes. Some people like their meats roasted, others do not care a tittle whether it is baked or gas-cooked; but it is clearly deception when a person is told that a piece of beef has been roasted which has instead been cooked in the gas oven. Neither does Dr. Hime seem to pay special regard to the important question of personal idiosyncrasy. If the quality of our food supply is to be state protected, with any degree of efficiency, that is a point which must not be lost sight of, for in all attempts to keep up the health of the community all sorts and conditions of men must be reckoned with. In conclusion, *The Lancet* hopes that a statute will very soon be introduced which shall definitely control all methods of coloring and preserving food.—*Pharmaceutical Journal.*

Futile Plague Precautions.—The *Medical Press*, writing on the above subject, says: "For ridiculous inadequacy it would be difficult to surpass the measures adopted in most foreign ports to prevent the importation of plague when these are limited to fumigation of the clothing of the passengers and crew, and the so-called disinfection of the ship. The very idea of disinfecting a ship strikes one as preposterous in view of the myriad of corners and subdivisions which no process of purification can be expected to reach. An efficient medical examination of the personnel and the isolation of suspicious cases for a suitable period are unquestionably the only effectual means of control. The more popular measures merely induce a fallacious confidence which may run counter to the very object for which they are carried out."

Extemporaneous Methods of Water Purification.—Surgeon-Major Schucking of the Austrian army is of the opinion that of the various methods of purification there are only two that can be taken into account for the use of troops in the field: (1) filtration; (2) purification by the addition of chemical agents. Among filters aiming at the sterilization as well as the clarification of water, the Berkefeld-Nordtrueyer alone is so constructed as to meet the exigences of war. But although well adapted for use in field stations, it can only be carried in baggage wagons. Portable filters only clarify muddy water. The use of them therefore requires to be supplemented by some means of destroying micro-organisms. After extensive experiments and researches (Traube, Lode, Kratschmer, Vogel) such a means has been found in hypochloride of chlorine. This chemical agency certainly kills all bacilli in thirty minutes.—*British Medical Journal.*

Concurrence of Typhoid and Malarial Fever.—In view of the statement made in Osler's "Principles and Practice of Medicine" that among a large number of cases of typhoid in which blood examinations were made, in not a single instance were the plasmodia of malaria found, although many patients came from malarious districts, it is well to note that Major M. T. Yare, R.A.M.C., records a case of apparently mild but well-marked typhoid in which the malarial parasite was discovered. From about the twenty-first day his blood was examined and a few crescents were seen, but very few. About a week later, however, he had rigors followed by shivering and then numerous pigmented parasites of the kind figured by Marchiafava and Bignami as pigmented malignant quotidian were found.—*Hospital.*

An Analysis of Ice Cream.—Additional information as to what may be found in that fearful and wonderful concotion sold as ice cream, has been obtained from a recent analysis of samples taken in London, and at Ramsgate, Margate, Dover, and Herne Bay. Some of the samples were obtained from shops. As is well known there is neither milk nor cream in this frozen stuff; boiled starch and maize being the principal ingredients. Some contained gelatin or size, also traces of lead, zinc, and antimony, and others were flavored with acetate of amyl which is extracted from fusel oil, and will produce headache, drowsiness, sickness, and stupor in children. Microbes, it need hardly be said, were found in abundance.—*Tit-Bits.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended October 19, 1900:

		Cases.	Deaths.
Smallpox—United States.			
Kentucky, Lexington	October 6th to 13th	1	
Louisiana, New Orleans	September 30th to October 13th.	1	1
Minnesota, Minneapolis	October 6th to 13th	2	
Nebraska, Omaha	September 30th to October 6th.	1	
Ohio, Cleveland	October 6th to 13th	9	
Utah, Salt Lake City	October 6th to 13th	10	
West Virginia, Wheeling	September 30th to October 6th.	1	
Smallpox—Foreign and Insular

MODERN QUARANTINE IN ITS RELATIONS TO PASSENGERS, CREW, AND CARGO.[1]

By ALVAH H. DOTY, M.D.,

HEALTH OFFICER, PORT OF NEW YORK.

For some years past the conviction has been forced upon me that a careful review of the subject of public health, particularly that part of it which relates to marine sanitation, will show that many of the methods now employed in carrying out this important work are not in harmony with the facts which have been presented by scientific investigation and practical experience, and I believe the time has come when this matter should receive the most serious consideration. The term "commerce destroyer," which has been applied to coast quarantine, has not been used without some justification, inasmuch as such rigorous and unreasonable regulations have been imposed in different sections of the world that commercial intercourse with those sections has been almost abandoned. In the past, excuse may have existed for the enforcement of these measures, as but little was known concerning the cause of infectious disease, the germicidal value of agents known as disinfectants, etc. However, the brilliant researches of Pasteur and of Koch twenty years ago, and the subsequent investigations of other savants, have given to the world indisputable evidence of the germ origin of many of the infectious diseases and have stimulated bacteriological inquiry in all directions. As a result, regarding this subject, we are now in possession of definite scientific knowledge which is in harmony with our practical experience. Therefore but little reason exists for the continuation of some of the methods at present employed in sanitation. If we profess a sanitary science we must abide by its teachings. In other words, we must have the courage of our convictions, no matter to what extent they may conflict with theory. Unfortunately the latter plays a prominent part in many of the quarantine regulations now in force, and while it adds nothing toward protecting the public health, it seriously injures commerce.

Contrary to the popular belief, the most careful investigation both from a scientific and a practical standpoint has demonstrated that the clothing actually worn by well persons is not a medium of infection. This is also true of ships' cargoes. In making this statement, I do not mean to imply that it is not within the bounds of possibility for exceptions to present themselves, but such instances are rare and should not be given undue weight in the consideration of this matter; exceptions confront us many times in public health work. For instance, it is generally accepted throughout the world that the maximum period of incubation of smallpox is fourteen days, and it is for this period that persons who have been in contact with the disease are kept under observation by the health officials. Reliable evidence, however, has occasionally been presented which tends to show that the appearance of smallpox may be delayed until the fifteenth or sixteenth day after exposure. Again, we accept five days as the maximum period of incubation of yellow fever, although instances are cited in which the disease has occurred after an incubation of six or seven days; still we are not justified in making rules and regulations to conform to these exceptions. In discussing this subject some time ago with a very distinguished health official, he emphatically indorsed the statement which I have just made regarding the clothing worn by well persons, and said that in his official experience covering a period of thirty-five years, he remembered but one case in which the clothing worn by a well person could have been regarded as the medium of infection. After an active experience of twenty years, I can bring to my mind but one instance of this kind. This occurred during the epidemic of typhus fever in 1893. I was not surprised, however, to find out subsequently that the man who had succumbed to the disease had been in direct contact with persons who at the time were suffering from typhus. During the different epidemics of smallpox, typhus fever, etc., which have occurred in New York, the physicians, ambulance drivers, and helpers connected with the health department have been in close contact with the patients; the ambulance drivers being frequently obliged to carry the sick in their arms. Nevertheless no evidence that I am aware of, after a careful investigation, has ever been presented to show that infection was carried either to the homes of these officials or to their associates. Cases of smallpox, typhus fever, etc., are frequently found which have passed through the various stages of these diseases before detection. In many instances, the relatives of these patients, living in the same apartments with them, who by successful vaccination or otherwise have become immune, are employed in factories where they are in close contact with others, yet without transmitting the disease. The busy medical practitioner may during the day visit many cases of infectious disease and may go from them to others without previously changing his clothing or performing disinfection. He has reason to believe that he does not act as a medium of infection; he sees no evidence of it in his own home, nor is evidence presented to him that he transmits disease to his patients. If under the circumstances which I have just cited the clothing worn by well persons does not act as a medium of infection, it is hardly reasonable to believe that danger exists in the clothing worn by those who are in good health and have been for a number of days or weeks removed from an infected port or other exposure. Bacteriological research goes far to confirm the results of practical experience to which I have just referred, inasmuch as it has shown that pathogenic organisms can continue their existence for only a few hours when exposed in the presence of sunlight and air. As a matter of fact, many careful observers believe that the activity, at least of some, of the specific organisms is inhibited by an exposure of only a few minutes to air and sunlight and that their activity and power of propagation are not renewed unless brought in contact with proper media. It is upon such evidence that we must base our conclusions in deciding what methods shall be employed to protect the public health.

[1] Read at the meeting of the American Public Health Association, Indianapolis, Ind., October 23, 1900.

As I have already stated, exceptions may exist, and occasionally evidence is presented to us from a reliable source which tends to show that disease is contracted through the medium of the clothing of well persons. It is reasonable to believe that when a person is in close and prolonged contact with a case of scarlet fever or smallpox, for instance, then puts on an outside wrap and removes it after going directly to another apartment but a short distance away, he may transmit infection. However, careful investigation, with the most reliable evidence, shows that this occurs only in rare instances. In connection with municipal sanitation the possibility that such instances may occur should receive proper consideration, and reasonable efforts be made to prevent their occurrence, whereas in marine sanitation this possibility need receive consideration only when infectious diseases actually exist on the arrival of the vessel in port. It is not proper nor does it aid in the advancement of sanitary science to overlook facts. The importance of a clear understanding of this matter, particularly in relation to marine sanitation, cannot be overestimated; it means, as a rule, that we can safely dispense with the disinfection of clothing actually worn by well persons arriving on vessels from infected ports; this not only lessens the detention of ships, but diminishes the expense to commerce. In municipal sanitary work this knowledge is valuable, as we are then reasonably assured that the disease will not spread—at least to any serious extent—through the medium of clothing worn by well persons; moreover, it teaches us to make a more thorough inspection in order to ascertain the origin of an outbreak of infectious disease. Such an inspection will frequently bring to light mild, ambulant, or convalescent cases which otherwise would not be found.

When we have given to the patient his clothing and effects, an apartment, and the required attention, and have surrounded the case with every possible sanitary precaution, and when at its termination we have performed careful and thorough disinfection, we have, I believe, given to the public the full protection which is dictated by practical science.

We have equally satisfactory evidence that a ship's cargo does not act as a medium of infection; if exceptions exist they have not been brought to my attention.

The outbreaks of bubonic plague in European and other ports with which the United States is in frequent and constant communication have brought prominently to our notice the question of the transmission of this disease by rats and other vermin. Our information on this subject is at present by no means complete; although Kitasato and Yersin demonstrated the presence of the disease in rats during the epidemic of bubonic plague in Hong Kong in 1894, we have beyond this but little authentic information on the subject. It is, however, reasonable to believe that in such communities as are found in India and China, where filth, overcrowding, and bad sanitary regulations exist to an extent which is almost beyond belief, the dissemination of infection is so general that even vermin are involved. However, in civilized communities where the ordinary sanitary regulations are carried out, the danger from this source would seem to be very limited. What may be a satisfactory summing up of this detail of the subject from a theoretical standpoint, although entitled to respectful consideration, should not overshadow the practical experience in this direction. So far as I am able to ascertain, no authentic report exists which shows that cargoes of vessels have transmitted bubonic plague through the medium of infected rats or other sources. Since 1870 this disease has been particularly active in India and China and other Eastern countries, where it has visited many important seaports. During this time both sailing-vessels and steamers have been plying between the ports referred to and the United States, carrying cargoes which come directly from the plague-infected districts, and which include raisins, rugs, silks, and other general merchandise. No quarantine restrictions whatever have been placed upon these cargoes, and in no instance has the disease been conveyed to this country. It would seem that a test of thirty years ought to be regarded as satisfactory evidence that bubonic plague is not likely to be transmitted in this manner, either by the cargoes or by the transportation of infected vermin. During the recent outbreak of the plague in Rio Janeiro and Santos, many vessels carrying coffee from these ports arrived at the New York Quarantine Station, probably two during each week, and for two months or more the cargoes were removed in open stream and transferred to the city on lighters, an opportunity thus being given to collect such rats, dead or alive, as could be found on board. These were removed to the laboratory and examined bacteriologically, and in no instance was there the slightest evidence of bubonic-plague infection. During the past six years about thirty-five thousand vessels from different parts of the world have entered the port of New York, and while, save in seven or eight instances, their cargoes have in no way been disturbed, yet not the slightest evidence has been presented that this material has in any way transmitted any form of infectious disease. I may add to this the fact that the most careful investigation has failed to present satisfactory evidence that either foreign or domestic rags act as a medium of infection, although they include all kinds of wearing-apparel which is frequently filthy and offensive. From what source, then, do we receive information which is supposed to give proof that the clothing worn by well persons or the cargoes of vessels act as a medium of infection? I believe it to be principally from vague reports, which have been handed down to us from almost ancient times. These reports, so far as my investigations are concerned, carry with them no scientific or practical proof, and are mainly hearsay evidence. For instance, an outbreak of infectious disease, the origin of which is unknown, appears at a small seacoast town. It is learned that a ship had previously arrived from an infected port, discharged its cargo, and departed; this appears to be a satisfactory explanation and it is decided that the disease was probably introduced by the cargo; but little or no attention is paid to the fact that on the arrival of the vessel the passengers and crew were not subjected to an examination, and that nothing is known of the possible existence of a mild case of infectious disease which may have remained in town or departed with the vessel. The license which theorists assume in dealing with this matter is apparently without any limit. Some time ago a foreign health official very gravely asserted that an outbreak of bubonic plague was caused by the transmission of infection through the medium of some neckties. Other statements are made regarding the origin of outbreaks of infectious disease which are equally ridiculous. No fair evidence is presented to substantiate such theories, which go far toward making public sanitation a farce. I believe that the future will show that if a vessel arrives in port and there are no cases of sickness present on arrival and none have occurred in transit, the vessel and its cargo will in no way act as a menace to the public health. From my own experience I am satisfied that this is true, and I believe that an outbreak of infectious disease when the cause is unknown is almost always due to the presence of mild, ambulant, or convalescent cases which have passed unrecognized. These constitute a great danger to a community inasmuch as there is no protection against them. Cases of smallpox occur in which the patient is apparently well and the eruption is with difficulty recognized. The frequent ex-

istence of mild cases of diphtheria is known to all physicians; mild or walking cases of typhoid fever which are mistaken for malaria, colds, etc., are well-known causes of serious outbreaks of this disease. The frequency with which mild cases of yellow fever occur is notorious; a vessel which arrived at this station some time ago from a port infected with this disease brought a large number of passengers, many of whom were not immunes; these were removed to Hoffman Island for observation and to complete the period of incubation; at the final examination all reported well, and from a visual inspection apparently were so. However, when the thermometers were used, four of the passengers were found to have elevated temperatures and were detained; of these, three were subsequently found to have yellow fever, one case being so mild that the patient could with little exertion have attended to his duties had he been allowed to proceed to his home. At least he could have kept up and around without arousing suspicion as to his condition. Cases of bubonic plague frequently assume a very mild form; of the four cases of this disease which occurred on the steamship *James W. Taylor* arriving at this port from Santos, Brazil, on November 18, 1899, one was fatal and the body was buried at sea. On the arrival of the vessel at quarantine the facts connected with the death of the steward were reported. The remainder of the crew were assembled on deck, reported well, and from external appearance were so. Inasmuch as the vessel came from a plague-infected port and as the symptoms associated with the steward's death were suspicious, the crew were made to remove their clothing and were subjected to a careful inspection, including a glandular examination. At this inspection the characteristic local lesion and the glandular affection were found in three of the crew, and the diagnosis of bubonic plague was then made and afterward confirmed by bacteriological examination. The captain of the ship, who was one of the three members of the crew removed to Swinburne Island Hospital, stated that he felt bad only for a day or so while in transit, and was surprised when informed of the serious nature of the disease. It is possible for such a person arriving on a vessel from a port issuing a clean bill of health or believed to be free from quarantinable diseases, to pass an ordinary inspection, then proceed to some interior town, there to act as a medium of infection without being recognized as such.

I believe the lessons which we are to learn from the facts which I have presented are that mild or ambulant cases of infectious disease and convalescents from these diseases constitute a serious menace to the public health and are chiefly responsible for outbreaks which from time to time occur, and which cannot be accounted for; and that neither scientific investigation nor practical experience justifies us in assuming that either the clothing worn by well persons or a ship's cargo acts as a medium of infection except in such rare instances as I have referred to. The views which I have thus expressed as the result of my scientific investigation and practical experience are in harmony with the policy which I pursue in the treatment of vessels arriving at the port of New York. I believe this to represent scientific sanitation; and while it offers the full protection which we can give to the public, it also relieves commerce of unnecessary delay and expense, a most important consideration.

In the inspection of persons coming from infected ports, it is evident that the ordinary examination, which includes statements from the persons concerned, is not sufficient at all times to detect mild or ambulant cases. It appears to me that the most practical and important addition that we can make to the ordinary method of inspection is the use of the clinical thermometer. This has been in operation at this station for the past two years, and the most satisfactory results have been obtained in detecting mild or ambulant cases. Although I am firmly convinced that the maximum period of incubation of yellow fever is five days, there is no doubt that during the first day or so of the disease, persons affected may present themselves and pass an ordinary inspection. The use of the thermometer at this time, however, will almost always show an elevation of temperature sufficiently high to justify us in causing a longer detention. The statements of persons detained at quarantine cannot be depended upon, and at this station we accept them only as corroborative evidence. Persons from yellow-fever-infected ports, who are detained here to complete the period of incubation dating from the time of departure from the infected port, are never released until their temperatures have been taken. I have already cited one of the number of instances in which the disease has been detected in this manner. Passengers or crews coming from plague-infected ports are not released until their temperatures have been taken, no matter how long they may have been in transit. These are instances of the value of the use of the thermometer at this station. It is frequently necessary to take the temperature of a thousand or more persons on the arrival of a vessel here. Therefore I have constantly on hand forty or fifty first-class properly registered instruments. If these are unreliable, or the exposure is insufficient, this procedure is worthless. What are known as half-minute thermometers are not practical, as they are extremely delicate and break easily. It is very important that those whose temperatures are being taken should be watched carefully, as they frequently take out the instrument, keep their mouths open, or otherwise interfere with the proper registration. A very interesting fact has been observed in connection with this portion of the examination. A temperature of 100° F. does not necessarily signify an abnormal condition, as our records show that this temperature is frequently present in well persons, and is probably due to some slight or transient cause, as it commonly disappears within a few hours. A large percentage of the temperatures range from 99° to 99¼° F. in persons in a normal condition. However, the rules of this department now require the detention of all whose temperatures reach 100° F. or over.

I cannot conclude this article without a reference to modern sanitary regulations, the value of which has been so forcibly presented to us during the past two years. Since 1895 or 1898, the civilized world has been made uneasy by reports from India relative to the terrible ravages of the bubonic plague in that country, and the possibility of its appearance at European and other seaports has caused much apprehension. During the past two years, the disease has appeared at Oporto, Lisbon, Alexandria, Santos, Rio Janeiro, San Francisco, and Glasgow, but in no instance has it proved to be a serious menace to the public health, the outbreaks having been rapidly brought under control, and in all but one of the above places the disease has disappeared. In Glasgow, a city which has an enviable reputation for cleanliness and good sanitary conditions, the duration of the outbreak was exceedingly short, although the disease existed some time before it was recognized. Than the above no more conclusive evidence has ever been presented to show the absolute certainty with which outbreaks of infectious disease can be controlled when good sanitary conditions, thorough inspection and observation, and cleanliness are maintained.

Snake-Bite.—The patient should be kept quiet, encouraged and soothed, and his strength spared. Hot bottles should be applied to the heart. Estimate the dose of venom before making attempts to counteract it by any of the serums advised.—Warren.

INCINERATION *VS.* EARTH SINKS AND CHEMICAL DISINFECTION.

By WILLIAM G. BISSELL, M.D.,

BUFFALO, N. Y.

During the late Spanish-American War from among an enrolment of 182,687 volunteers, 4,015 died of disease. It has been conservatively estimated that this death rate represents about one-twentieth of the number sick with severe illnesses. If this be true, at least 80,300 men were totally unfit for duty for a greater or lesser period of time; and when it will be remembered that the prevailing illness was typhoid fever, and that many of the New York State regiments suffered as a consequence, it is not surprising that Col. Nelson H. Henry recommended to Major-General Charles F. Roe, commanding the National Guard of New York, that an independent investigation be carried on by the State of New York, to be entirely non-political, pertaining to the improvement of sanitary methods in camps of mobilization, so that if the National Guard of this State should again be called upon to serve as volunteers, they would not be subjected to the danger recently encountered. It has long been taught that typhoid fever is a preventable disease, and that its mode of transmission is by the ingestion of water or any food substance containing the bacillus of Eberth. During the late war there was little doubt that the earth interment of excrement was directly responsible for the ravages of this fever, in that it made it possible for the germ, if present, not only to contaminate the water supply, but to be deposited upon food substances by flies. The experience of the navy during this war fully corroborates this view, for although the men were cramped in quarters, and in a much warmer climate, they experienced little or no typhoid fever.

During the first year and a half of the Civil War typhoid fever was epidemic among the troops camped near Washington, and during 1861 and 1862 there was a morbility rate of 78.62 per thousand, and 19.55 per thousand succumbed to the disease. All this was known and thought to be understood when the troops entered the United States service in 1898.

Much has since been written and more stated about "inexperienced volunteers" being the cause of typhoid-fever infection in our army during the Spanish-American War. The truth of these statements might perhaps have some weight were it not a fact that the regulars likewise suffered.

Camp Alger in Virginia, a strictly volunteer camp, with a population of over twenty-five thousand National Guardsmen, occupying poorly selected ground, had but thirty-nine cases of typhoid fever at the end of sixty days occupancy of this camp. Had the troops been moved from this territory after six weeks, as they should have been, they would not have been subjected to the positive evils of the earth interment of excrement which had become, even at this time, an unpleasant feature.

It is the history of all wars, with the exception of the Franco-Prussian of 1870, which might be termed a "constant fight," that preventable diseases have caused more deaths than the bullet. The early Romans, thousands of years before the discovery of firearms, deposited their excrement in the soil, and at the time of the excavation of Pompeii a system of sewering was found constructed along the same lines as that in use in the cities of to-day. There has been no change in principle for excrement disposal from the earlier days up to the present time. Is it surprising that history has repeated itself?

Military camps have not alone suffered from the evil effects of the soil interment of excrement, and nearly any one can name towns which depend entirely upon the privy for its sewage disposal, that have as high a death rate from typhoid fever as did Camp Alger at the end of its occupancy.

I am not endeavoring to uphold the administration of this camp, but simply desire to demonstrate that it was not the "inexperienced volunteers" who were responsible for the transmission of typhoid infection, but rather the method, or better perhaps lack of methods, furnished these volunteers for the disposal of their offal.

The cities of to-day are doing away with the use of the privy. To be sure, a system is substituted which ultimately contaminates the water ways, and for this reason is far from the ideal. How much better it would be if every household had its individual device by which the offal could be completely consumed!

During the latter part of the Spanish-American War the army medical board began to appreciate the dangers of the earth sink and recommended as a substitute the use of zinc-lined wooden troughs containing milk of lime, into which the excrement was deposited, this mixture stirred, and after a time drawn off into tanks and carted to receive its soil interment. At about the same time this board considered the possibilities of the use of heat for the disposal of excrement. Several different devices were experimented with, and after a thorough trial of one month, as is stated in their report, they ventured the opinion that none of the methods tried during this time met the conditions of troops in the field as well as the above "milk-of-lime soil-interment process." This, no doubt, is true if we are to understand that moving bodies are meant by "troops in the field," for as a matter of fact moving troops are not subjected to the evil influences of the earth sink, and it is not necessary to exercise the same precautions. But exception can be taken if it is meant that the milk-of-lime method is more adaptable than burning in camps of mobilization. The use of milk of lime for the chemical reduction of sewage is not new. It coagulates albumin and forms an insoluble precipitate. This was the first process tried by the Commission on River Pollutions in 1868, and was pronounced by this commission to be a failure. The lime coats the bacteria and their spores, forming calcium carbonate. And many investigators have proven that when this outside portion of excrement is removed, the interior of a typhoid stool, for example, is capable of transmitting typhoidal infection. This method does not appeal to one from a labor-saving or pleasant standpoint. The use of milk of lime was the fundamental principle of the Suvern mixture formerly used in Leipsic.

Taking into consideration these facts, the New York State authorities decided to direct their efforts toward methods of incineration rather than chemical reduction for the disposal of excrement, as heat is recognized to be the best-known germicide. The object to be attained is the adoption of some method which will surely and completely consume human excrement in a pleasant and inexpensive manner if possible, but which will without fail prevent the transmission of infection from this source at any cost.

In May, 1899, the following circular letter was sent to many of the more experienced sanitarians of this country and Europe:

DEAR SIR: I have been informed by the New York State National Guard authorities that an opportunity is to be provided in the near future for a series of experiments to be conducted under my direction, pertaining to the practical application of methods of incineration of excrement and garbage, to be used by military forces in field service.

Should you have ideas on this subject, I will be greatly honored if you will acquaint me with same and will endeavor to put in practical operation any beneficial suggestions that may be offered. In the final report on this subject, special credit will be given those

persons offering suggestions that prove, in this connection, of value. Respectfully,

(Signed) WILLIAM G. BISSELL,
Bacteriologist, Department of Health, Buffalo, N. Y.

Of the replies received, many emphasized the necessity for a radical change from the present time-honored army method of excrement disposal, but few offered any practical suggestions.

A communication from Dr. Albert H. Gihon, the retired medical director of the United States navy, was the single exception.

He made reference to an incinerating apparatus, with which, after a comparison of the various types on the market, the New York State National Guard had previously decided to conduct tests.

Dr. Gihon stated that "an instrument I saw in Buffalo a couple or more years ago seemed to me to possess all the requisites, and to be particularly adapted for military field service."

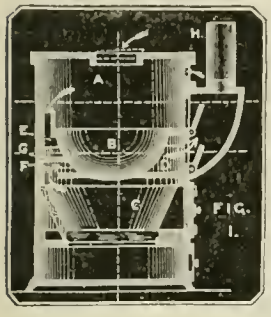

FIG. 1.—Interior View of Incinerator Showing Draught Construction.

The New York State authorities decided in 1899 to construct fifteen incinerators after the principle in question, and experiment with them during the tours of field duty ordered for the Seventh Regiment of New York and Twenty-third Regiment of Brooklyn. These regiments established camps in the near vicinity of the State grounds at Peekskill, and disposed of all their offal by the use of the experimental device.

The accompanying illustration plainly shows the construction of the incinerators, of which *A* is the upper space between the pot or receptacle *B* and the top of the casing; *C* is the fire-box, and *D* is the draught passage; *E* is a passage leading down from an upper space *A* into the draught passage *D*, and *F* is an opening leading from the fire-box up into the draught passage *D*. A deflecting wall *G* is located midway between the passage *E* and opening *F*. The odors from the material in the pot or receptacle are drawn down through the passage *E* by the draught, as indicated by the arrows, and pass through the draught passage *D* into a chimney or smoke pipe *H*, and the products of combustion from the fire-box *C* pass up through the opening *F* into the same draught passage *D*, mingling therein with the odors and gases from the upper space *A*, which are destroyed before passing into pipe *H*.

For use, the incinerators were placed in a convenient location, and pieces of pipe three feet in height were attached to portions, as shown in diagram at *H*. At the time of incineration, the wooden seat supplied with each instrument was replaced by an iron cover. The draught near the smoke-pipe was opened and fire made by using wood as fuel.

These devices were built of the best cast iron, having a steel jacket with asbestos lining, and weighed approximately three hundred pounds each. As to whether they were a success or not will be shown by the attached communications which were received from the medical officers of the Seventh and Twenty-third Regiments.

MEDICAL DEPARTMENT,
SEVENTH REGIMENT, N. G., N. Y.,
PARK AVE. AND 66TH STREET,
NEW YORK, June 30, 1899.

Major William G. Bissell, Surgeon Seventy-fourth Regiment, N. G., N. Y., Buffalo, N. Y.

SIR: I have the honor to acknowledge the receipt of your letter of June 28th. In response thereto it gives me much pleasure to state that from my observation of the incinerators used under your direction in the recent camps of the Seventh Regiment at Crofts' Farm and Lake Oscawana, I have no hesitation in pronouncing them most satisfactory. Of course, I understand that these particular incinerators were not built for military purposes, nor was easy and rapid transportation greatly considered in their construction. But they certainly do completely and rapidly reduce excrement and garbage to ashes without odor, and thus demonstrate their great value for military camps, both from a labor-saving and sanitary point of view.

Could they be considerably reduced in size and weight and be mounted on some sort of low vehicle for quick transportation, their usefulness would be greatly enhanced. Respectfully,

(Signed) CHRIS. J. COLLES,
Assistant Surgeon Seventh Regiment, N. G., N. Y., Acting Surgeon.

MEDICAL DEPARTMENT,
SEVENTH REGIMENT, N. G., N. Y.,
PARK AVE. AND 66TH STREET,
NEW YORK, June 30, 1899.

Major W. G. Bissell, Surgeon Seventy-fourth Regiment, N. G., N. Y., Buffalo, N. Y.

SIR: I have the honor to report that I observed carefully the incinerators in use at Crofts' Farm and Lake Oscawana during the camp of the Second Battalion of the Seventh Regiment, N. G., N. Y. I found that the faces deposited in these had been entirely consumed, that the fourteen in use were quite sufficient, that by their use the digging of sinks was made entirely unnecessary, that a possible source of danger to the battalion was absolutely removed, and that the hygienic condition of the camps was therefore notably improved. If the incinerator could be made more portable and could be mounted on low wheel-trucks suitably covered and screened, the practical use of the apparatus would be furthered. Respectfully submitted, (Signed) JOHN H. HUDDLESTON,
Assistant Surgeon, Seventh Regiment, N. G., N. Y.

CASTLETON, VT., July 4, 1899.

Major W. G. Bissell, Buffalo, N. Y.

SIR: Your letter of June 28th, asking for my personal opinion in regard to the incinerators which were tried during the march of the Second Battalion, has just been received, having been forwarded from Brooklyn.

I was very much pleased and surprised at the success of the trial to which the incinerators were put. Only ten were used, and no sinks were dug; the number was sufficient for the battalion.

During their use there was no perceptible odor or anything that could be considered in any way objectionable.

The incineration of excrement was all done after the battalion had left the camp, so that I did not have an opportunity of seeing that process.

The only suggestion that I have to make is that the incinerators are too bulky and heavy as now made. If made one-half the size and weight, they would be much easier of transportation, and would be large enough for the uses intended. Respectfully,

(Signed) HENRY L. COCHRAN,
Surgeon Twenty-third Regiment, N. G., N. Y.

In accordance with the suggestion that a reduction in size was desirable and the necessity for some class of vehicle for the easy transportation of the incinerators, in the early part of 1900 Gen. Edward M. Hoffman, Adjutant General, S.N.Y., authorized the construction of sixteen incinerators, to be three-fourths the size of those previously experimented with, which allowed of a reduction in weight of one hundred

pounds for each machine, but still maintained a capacity of five gallons to each incinerator.

A contract was entered into with the International Garbage and Excrement Incinerator Company of Buffalo, who built the machines after the suggestions offered. Transportation plans and specifications were submitted to the Harvey Carriage Company, who constructed two wagons carrying eight incinerators each. One wagon was given a thorough trial on the tours of field service from the State camp of instruction of the Eighth, Ninth, Twelfth, Fourteenth, Twenty-second, Forty-seventh, Sixty-ninth, and Seventy-first Regiments. The specification of these wagons was as follows:

NEW YORK STATE WAGON, FOR TRANSPORTATION OF EIGHT (8) INCINERATORS.

Body: Length of body, 15½ feet. Width at ends of body, 4½ feet. Width at centre of body, 6 feet. Height of body, 6½ feet. Sills and frame of body to be constructed of iron. Sills, 2½ inches angle iron; frame, 1½ inches by ⅜ inch. Floor of wagon to be "skeleton" structure, of sheet iron. Floor iron stringers, 2 inches by ½ inch. Sides, ends and top of body to be 16 inches gauge, best quality sheet steel. Rear end of body to have a neatly finished door, 6 feet by 2 feet 10 inches wide. The forward end of body to have a neatly finished window.

Gear: Platform gear, with platform springs, front and back. Springs, 2 inches wide; 8 plates 40 inches long.

Axles: Concord axles, 1⅝ inches by 10 inches.

Wheels: Sarven Wheels. Front wheels to be 3 feet high, 2⅛ inches spoke, 10 inches hub, 1¾ inches rims, 3 inches tread. Hind wheels to be 4 feet high. Other material same as front wheels. Tire 3 inches wide by $\frac{3}{16}$ inch thick.

Painting of body and gear to be of light gray dressing, with asbestos fireproof paint. Workmanship of wagon to be of the best quality. Height of wagon, over all, above ground, not to exceed 8½ feet. Weight of wagon, with load, not to exceed 3,500 pounds. Track of wagon to be 5 feet. Pole of wagon to be constructed of best quality of ash, as also the whiffle trees and cross tree. Forward end of pole to have hook attachment with chains. Wagon to be constructed with serve of brakes for rear wheels, to be operated from driver's seat. Interior of wagon to contain box on either side of entrance, neatly constructed, for transportation of fuel. Front partition of body of wagon to be constructed at such a distance as to allow of a driver's seat; same to be of such structure to permit of transportation of small tentage, etc. Top of wagon to be ventilated. One lamp on interior. Two lamps on exterior. Four metallic rolls for toilet paper in each wagon.

The "march outs" from the camp of instruction consisted in the establishment of a camp near Lake Mohegan, a distance of about nine miles, and each regiment remained there for a period of three days. The incinerators constructed by the State in 1899 were placed in service in addition to the new wagon. This afforded seating facilities for twenty-three persons at the same time, and permitted the collection of one hundred and forty-five gallons of excrement before the destructive process began. In accordance with army custom the seating capacity of any sink should represent at least eight per cent. of the strength of commands, and it can be understood that the number of incinerators in use during this second investigation were taxed to their utmost, as they represented a little over four per cent. of the average number of the troops present.

Incineration was accomplished daily during a period of one month. During the greater part of this time little or no odor was perceptible, notwithstanding the fact that in many instances the climatic conditions were most unfavorable. The fuel used was unseasoned wood, mostly birch with some oak, and was not such as would furnish the hottest fires with a large flame. Failure to incinerate was never experienced, but in several instances some odor was noticeable, this being occasioned when the flame was not sufficient to carbonize the gases, *i.e.*, indol, skatol, and members of the marsh-gas series, as they repassed through the fire pit.

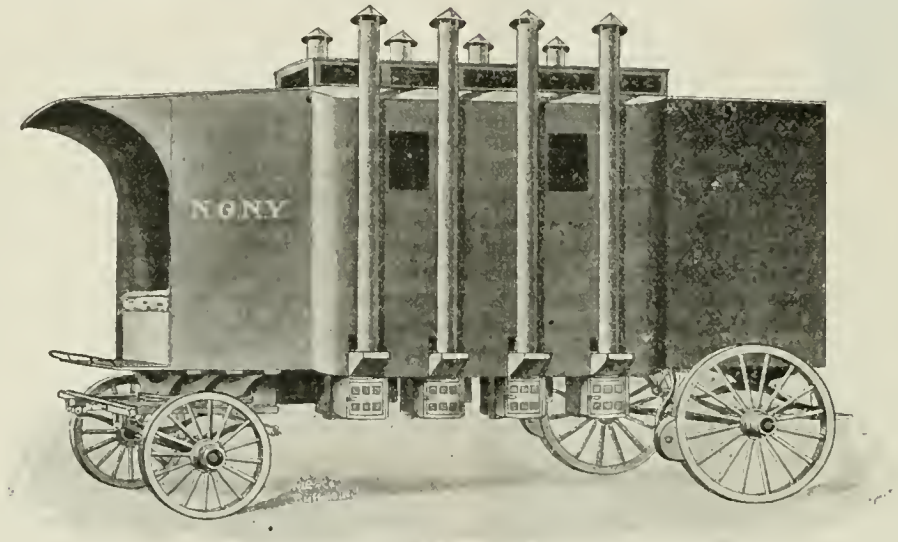

FIG. 2

In order to incinerate without odor it is necessary to have a quick live flame, and it was found that the application of a small amount of tar or oil would materially assist in this connection. Soft pine wood was found to be the best fuel. When odor did occur during the destructive process it was never sufficient to offer a serious objection to the use of the incinerators, as it lasted but a short time and never equalled that which is experienced during the use of an old earth sink. It was decided that for a regiment of six hundred men about four wagons, furnishing thirty-two incinerators, would be required to permit of the daily incineration of all offal.

In August of the present year the Sixty-fifth Regiment, N. G., N. Y., effectually destroyed the excrement from over five hundred men during a tour of field

service of seven days by the use of two wagons, each containing eight incinerators; and in an official report Major Albert H. Briggs, surgeon, who during the Spanish-American War was the sanitary inspector of the Second Army Corps, states: "It is my opinion it (incinerator) is the only proper way to dispose of excrement in camps. I think it would suppress if present and prevent the outbreak of typhoid fever, cholera, etc." That the views of the surgeons who accompanied the troops during the "march-outs" from State camp might be received, the following blank form for report was mailed each organization, and the filled-in copy from Nelson H. Henry, chief surgeon of the Guard, is submitted as example.

Statement from Nelson H. Henry, Surgeon N. G., N. Y.

1. (*a*) Do you consider the use of incinerators, such as operated during the "march-outs" at State Camp during 1900, an improvement over the old earth-sink method for the disposal of excrement? Most decided progressive step and great improvement.

(*b*) Please state reasons for your opinion. A positive and infallible destruction from infection from such source.

2. During collection, in which instance is there the more odor: (1) In vicinity of incinerators, or (2) in vicinity of earth-sinks? The latter.

3. (*a*) Do you consider the odors that arise occasionally under certain conditions during burning of incinerators a decided objection? No; as such odor is harmless.

(*b*) Please state reasons for your opinion.

4. In your judgment would the complete daily incineration of all the excrement in camps of mobilization have a marked influence in preventing typhoid fever? I certainly consider that such plan would minimize the danger of infection and prevent the extension of typhoid fever.

It is the almost universal opinion that incineration is far more efficient for the final disposal of excrement in camps of mobilization, and less objectionable as regards labor, odor, etc., than the use of the "zinc trough milk of lime" or any other device, and would to a greater certainty eliminate the opportunities for camp pollution and render the occurrence of typhoid fever and other preventable diseases almost impossible. The following report was submitted by the United States army detail to the Camp of Instruction for the season of 1900:

ARMY AND NAVY CLUB OF NEW YORK CITY.
July 3, 1900.

Major William G. Bissell, Seventy-fourth Regiment, N. G., N. Y.

SIR: Before completing my tour of duty with the National Guard of New York, I desire to express to you, as sanitary officer of the Camp of Instruction, at Peekskill, and the sub-camp near Lake Mohegan, N. Y., my unqualified approval of the incinerators used by you to dispose of the fecal matter at the latter camp. It is not necessary for me to state here, in detail, all of the advantages of this method of disposing of fecal matter; it is enough to say that I believe your method would be an excellent plan to adopt, especially for large or permanent camps or camps of mobilization.

I want also to state that I observed the operation of your incinerators, both stationary and movable, under nearly every imaginable condition, and that their work was satisfactory. Very respectfully,

HENRY G. LYON,
Captain Twenty-Second U. S. Infantry.

The wagons built by the State, although not ideal as at present constructed, many points requiring alteration, received the highest commendation as to the principles involved.

There seems to be little doubt, according to the views expressed by persons familiar with the progress of the investigation, that the military authorities of the State of New York have discovered a method by which the occurrence of typhoid fever among its troops will be materially lessened, and too great credit cannot be given Major-General Roe and the members of his staff for their untiring efforts in furthering this investigation.

The military authorities of the world are becoming interested in this work, and the following letter is a sample of the many inquiries received during the past few months:

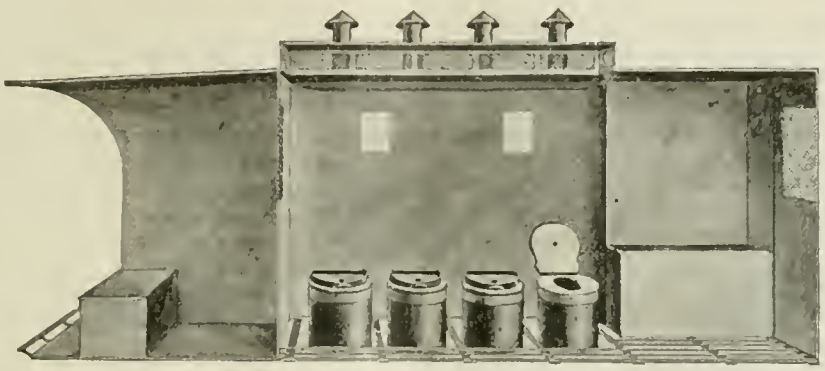

FIG. 3.—Picture of Interior of Wagon.

MILITARY ATTACHÉ BRITISH EMBASSY,
WASHINGTON, August 22, 1900.

Major William G. Bissell, Surgeon, Seventy-fourth Regiment, N. G., N. Y.

MY DEAR SIR: The attention of the British war office has been called to the portable incinerator invented by you, and which, I think, I had the pleasure of inspecting at Peekskill camp last year. The director-general of ordnance in London is anxious to obtain one of these incinerators for trial, and has directed me to find out where one could be purchased, and particulars of the price, etc. Yours very truly,

A. H. LEE,
Lieutenant-Colonel Military Attaché, British Embassy.

There is one thing certain, just so long as the antiquated earth method for the disposal of excrement is practised in military camps of mobilization, just so often will history repeat itself as regards the ratio between deaths from preventable diseases and bullets. Instead of continued government expenditures in investigating armor plate, projectiles, etc., a much more profitable result could be obtained by inaugurating improvements for camp sanitation.

Let the Spanish-American War at least be the Na-

tional Guardsmen's object lesson, and if no other remedy can be had, let the National Guards of the individual States inaugurate methods for the protection of the "inexperienced volunteer."

SOME CASES OF ACUTE APPENDICITIS.[1]

By ALEXANDER B. JOHNSON, M.D.,
SURGEON TO THE NEW YORK HOSPITAL.

Among some forty cases of acute appendicitis operated upon by the writer during a period of rather more than one year, there are certain ones which appear to him worthy of record on account of unusual complications, and certain others in which recovery took place in spite of extensive involvement of the peritoneum in the inflammatory process.

These latter appear to the writer to demonstrate fairly well the value of abundant saline irrigation of the peritoneal cavity through a moderate incision and without evisceration, in cases of widespread purulent peritonitis.

The following list exhibits the various types of the disease:

Number of cases, 40. Number of deaths, 5. Mortality, 12 ½ per cent.

Causes of death: 1. Acute appendicitis, perforation, general purulent peritonitis, shock.

2. Acute appendicitis, perforation, general purulent peritonitis, peritoneal sepsis.

3. Acute appendicitis, perforation, general purulent peritonitis, nephritis, septic diarrhœa, exhaustion.

4. Acute appendicitis, perforation, localized peritonitis with abscess, acute mesenteric lymphangitis, suppuration of the retro-peritoneal glands, septic pneumonia, pyæmia.

5. Acute appendicitis, abscess, intestinal paresis, persistent vomiting.

Types of the disease: Acute appendicitis, perforation, progressive purulent peritonitis—3 cases, 3 recoveries.

Acute appendicitis, perforation, progressive fibrino-purulent peritonitis—3 cases, 1 death.

Acute appendicitis, perforation, general purulent peritonitis—8 cases, 3 deaths. Mortality, 37 ½ per cent.

Chronic appendicitis, abscess, intestinal obstruction by bands—1 case.

Acute appendicitis, localized peritonitis, abscess filling the pelvis—9 cases.

Acute appendicitis, gangrene of the appendix, abscess, suppurative mesenteric lymphadenitis, pyæmia—1 case, death.

Acute appendicitis, gangrene of the appendix, circumscribed abscess—12 cases.

Acute gangrenous appendicitis, localized peritonitis—3 cases.

Acute appendicitis, localized peritonitis—1 case.

Acute appendicitis, recurrent, abscess—1 case.

The appendix was removed in 34 cases.

In 6 cases the appendix could not be identified, and the duration and character of the inflammatory process were such as to lead to the belief that the appendix was destroyed.

No previous attacks in 30 cases. Several attacks in 4 cases. Relapsing appendicitis in 2 cases. Two attacks in 2 cases. One previous attack in 1 case. Nine previous attacks in 1 case.

The number of cases which may be fairly described as cases of general purulent peritonitis were eight. Three of these were fatal—a mortality of thirty-seven and a half per cent. The number of cases of progressive purulent peritonitis accompanied by only a small amount of fibrinous exudate, in which a large part of the peritoneum was the seat of purulent inflammation, but in which a considerable area remained free from infection, numbered three with three recoveries. The cases in which an extensive fibrino-purulent exudate existed, but in which a considerable part of the abdomen was protected more or less perfectly by adhesions, numbered three with two recoveries and one death. The remaining cases included several in which unusual complications existed, and among them were also several in which an extensive but strictly limited fibrino-purulent exudate existed among the intestines.

To avoid misunderstanding I desire to define the pathological condition which I have characterized by the designation "general purulent peritonitis." By this I mean cases in which fluid, purulent in character and not merely cloudy serum, appears, at the time of operation, to occupy the pelvis, both flanks, the region beneath the liver, the region of the spleen, the general surface of the small intestines, and in some cases the space between the liver and the diaphragm.

In none of the cases operated upon was the lesser cavity of the peritoneum explored, and I suppose that, at least in those cases which ended in recovery, it is safe to assume that the peritoneum lining this cavity was healthy; and this being the case, I cannot quarrel with those who upon a strict anatomical basis assert that the cases operated upon were not cases of general peritonitis.

In addition to the purulent exudate, flakes of fibrin were present in greater or less amount, partly free and partly attached here and there to the peritoneal surface which appeared in the wound.

In some of the cases the coils of intestine which presented themselves near the wound were distinctly inflamed and more or less dull in appearance; in some the peritoneal surface seen was injected, but not dull. In all, the intestines were distended to a greater or less extent.

The method of operation was the same in the cases of general purulent peritonitis without much fibrin and the cases of fibrino-purulent peritonitis with more or less distinct limitation of the infected areas. The incision was from three to four inches in length, made parallel with the fibres of the external oblique aponeurosis between the outer border of the right rectus muscle and the iliac spine, with this bony point opposite its centre. In two cases a second incision was made upon the opposite side of the abdomen, and in these a widespread fibrinous exudate existed, and the barriers between the separate foci of pus were unusually firm.

When the abdomen was opened and it was noted that the belly appeared to be infected in all directions, the appendix was sought for and removed as rapidly as possible. The stump was usually inverted in the centre of a catgut purse-string suture, reinforced in cases in which the wall of the cæcum appeared infiltrated and friable with one or more mattress sutures of the same material. The cautery and catgut ligature were employed in some cases.

The appendix being disposed of, the various regions of the abdomen were carefully explored in turn to determine the extent of peritoneal invasion. The pelvis, being the commonest site, was explored with a gauze pad on the end of a holder, and if a purulent collection was detected, a long glass tube open at one end and five-eighths of an inch in diameter was inserted to the bottom of the pelvis, and through it a quantity of hot sterile salt solution at a temperature of 116° or 118° F. was allowed to flow from an irrigator held about four feet above the patient's body.

The wound was held open with the left hand during the irrigation, and the tube was moved about with the

[1] Read before the Surgical Section of the New York Academy of Medicine, October 8, 1900.

right hand, gently breaking up any adhesions, and the washing was continued not only until the water returned perfectly clear, but for a while thereafter.

The ascending colon and the region beneath the liver were then explored, and if found infected they were washed out in a similar manner. Next, a sponge holder containing a pad of gauze was pushed across to the opposite iliac region and flank, and if pus appeared these regions were treated in the same way.

Next, after exploration the tube was pushed in the direction of the spleen, and then to the anterior surface of the stomach in front of and behind the omentum, and then into the space between the liver and the diaphragm.

Lastly, the pelvis was again thoroughly irrigated and then gently dried with large, loose masses of sterile gauze pushed down with a sponge holder, the intestines being meanwhile protected as far as possible with the fingers of the left hand. No intestines were removed from the cavity of the belly at any time, and during the manipulation their escape was prevented by the left hand held over the wound. The fibrinous plaques which sometimes covered the coils of gut were not disturbed.

A large glass drainage tube was then inserted to the bottom of the pelvis and repeatedly packed with sterile gauze strips, until no more fluid appeared upon the gauze. In some cases a second glass tube was passed upward along the ascending colon. A small strand of iodoform gauze was then inserted to the bottom of the tube in the pelvis, and another small strand was sometimes led from the base of the appendix outward. The superficial wound was then loosely packed with sterile gauze to keep it open and to permit the escape of any free fluid which might find its way to that neighborhood. A voluminous dressing was then applied. The packing in the glass drainage tube was replaced four times during the first twenty-four hours; there was usually a profuse watery discharge into the external dressings, which were changed as often as they became soiled. If the patient did well the glass tube was removed on the third day; and if any fluid appeared still to accumulate at the bottom of the pelvis, a strand of iodoform gauze was placed in situ through the tube and held in position by a probe while the tube was being withdrawn. In general it was noted that those patients whose entire belly was washed in the manner described suffered but little or not at all from shock. The pulse was even diminished in frequency and improved in quality in some of the cases when the irrigation was finished.

In several cases in which there was an elevated temperature at the time of operation, the thermometer showed a drop nearly to normal in a few hours. An example of this is offered by Case XXV., one of general purulent peritonitis in a boy eighteen years old, operated on during the third day of the attack. At the time of operation his temperature was 103.6° F.; pulse, 120. Within six hours after the operation his temperature fell to 99.6°, his pulse to 90, and there were only trifling elevations of temperature thereafter.

A similar improvement in the general condition soon after operation was noted in all the patients who recovered, except one. In this case (No. XXXIII.), in addition to a general purulent peritonitis, the patient, a boy of nine years, was suffering from an intense degree of septic absorption together with intestinal paresis which bade fair to prove fatal. His temperature remained high, the amount of discharge from the wound was large, he was unconscious for four days; then improvement became manifest, and he eventually recovered.

The only case in which the operation seemed to add markedly to the shock already existing was Case VIII. A man aged thirty-nine years, suffering from typical peritoneal sepsis, was operated on about thirty hours after the infection of the belly had become general. At the time of operation his temperature was subnormal; pulse, 130. The general condition was very unfavorable. He died in two hours.

The ordinary method of subcutaneous and rectal stimulation was used in such of the cases as seemed to require it. Irrigations of the lower bowel with salt solution repeated every few hours appeared to do good in certain instances. The injection of sulphate of magnesia into the gut through the abdominal wound at the time of operation was not practised. Calomel in minute doses frequently repeated, or sulphate of magnesium used in the same way, together with enemata, was depended upon to produce early evacuations of the bowels. Their use was commenced in from twenty-four to forty-eight hours from the time of operation.

Several of the patients who recovered appeared at the time of operation to be in a most unfavorable condition; not only were there present the signs of severe sepsis with its concomitant symptoms of a rapid pulse of poor quality and a septic facies, but the appearance of the interior of the abdomen was in several instances exceedingly unfavorable.

I am inclined to think that had the intestines been removed from the belly and washed and wiped, the patients would not have recovered. It seems at the present time hardly necessary to mention this method of treatment in cases of purulent peritonitis except to condemn it, and yet I am informed that several prominent surgeons in this country are still in the habit of practising it.

Granting that a certain proportion of these patients recover after evisceration, yet I am inclined to think that the same good result might have been accomplished by less dangerous means. All who have tried this method must admit not only that the immediate effect of such procedures is a severe strain upon the already lowered vitality of the individual, but also that subsequent paresis of the bowel is a not uncommon and dangerous sequence. Of course, the septic process itself is a frequent cause of paralysis of the gut, but I have more than once had the opportunity of observing the condition of a much-handled coil of intestine, healthy at the time of operation except for a perforating wound necessitating suture; while five days and more after the original operation I have seen such a coil distended, intensely congested, flabby, its muscular coat evidently paralyzed, although the interior of the belly had apparently remained quite aseptic.

In the twenty-six cases in which the involvement of the abdomen was less extensive and was strictly limited, there were presented, as already noted, several different types of the disease.

The operative technique employed was a moderate or small incision; in the cases which appeared before operation to be milder in type, the intermuscular incision was used. No effort was made, in abscess cases, to avoid opening the healthy peritoneal cavity. When the presence of pus was suspected the healthy coils of gut were protected in the usual manner with gauze pads. The abscesses were slowly and cautiously evacuated, though the fear of opening up healthy regions did not prevent a persistent search for the appendix.

A few cases presented such dense adhesions as to render extensive dissection dangerous to the integrity of the gut. They were all old cases of abscess in which it appeared probable that the appendix was largely destroyed. The writer is not aware that any of these patients suffered from subsequent attacks, although he has made no especial effort to acquaint himself with their later histories.

In the cases presenting large abscesses which extended to the bottom of the pelvis, irrigation of the abscess cavity as before described was practised, and

a glass drainage tube was inserted during the first forty-eight hours.

Whenever it appeared safe, the abdominal wound was sutured in part. A small strand of iodoform gauze was led out from the stump of the appendix, and if no purulent discharge occurred it was definitely removed in from four to seven days. Among these twenty-six cases there was one death. The history of this case will be given later.

Among the forty cases there were four in which the appendix having been removed, a small fecal fistula formed in the wound, to close spontaneously after a period varying from one week to a month. Among the six cases in which no appendix was found there occurred one fecal fistula, which closed spontaneously in a short time. In one case a large fecal fistula occurred apparently from the sigmoid flexure or rectum. It closed after curettage some months after the operation.

Two cases presented complications of an unusual character. Their histories are numbered XI. and XXXVII.

Case I.—Acute appendicitis, progressive fibrinopurulent peritonitis, secondary subdiaphragmatic abscess; recovery. Joseph N——, male, aged sixteen years, admitted April 9, 1899. First attack. Duration three days. Onset sudden. General abdominal pain, localized after twelve hours in the right iliac fossa. Vomiting.

Examination: Abdomen distended and tympanitic. Muscular rigidity marked on the right side. Temperature on admission, 103.8° F., pulse, 120.

Operation: Appendix situated behind the colon. Much pus filling the pelvis and extending upward as far as the liver. Limiting adhesions imperfect. Saline irrigation of the entire belly.

Pathology: Appendix strictured one inch from base, beyond which it was gangrenous and perforated, containing two concretions.

Glass-tube drainage in pelvis, gauze drainage along the colon from below. Normal course until the tenth day, when a marked rise of temperature occurred, accompanied by abdominal pain and tenderness at the free border of the ribs on the right side.

Second operation on the fourteenth day. Vertical incision from ribs three inches downward through the rectus. Large collection of stinking pus evacuated from between the liver and the diaphragm. Slight fecal fistula followed from colon, which gradually closed. Normal recovery.

Case II.—Acute gangrenous appendicitis. John D——, male, aged nineteen years, admitted August 8, 1899. No previous attack. Duration four days. Onset sudden. General abdominal pain, localized after six hours in the right iliac fossa. Vomiting. On admission normal pulse and temperature. Abdomen not distended. Muscular rigidity not marked. Appendix felt low down close to Poupart's ligament. Appendix as large as an index finger. Entire mucous membrane gangrenous. Gauze-wick drainage. Normal wound-healing.

Case III.—Acute appendicitis, localized peritonitis. Kate W——, female, aged sixteen years; no previous attacks. Duration of present attack one week. General abdominal pain, localized after twenty-four hours in the right iliac fossa. Vomiting and constipation. Intermuscular operation. Distal end of appendix obliterated. Proximal end acutely inflamed. Gauze-wick drainage. Normal wound healing.

Case IV.—Acute gangrenous appendicitis, localized peritonitis. Charles J——, male, aged eighteen years. Nine previous attacks; none of them severe. Duration of present attack three days. General abdominal pain, localized after twelve hours in the right iliac fossa. Vomiting. Intermuscular operation. Appendix greatly enlarged. Gangrenous near its tip. No perforation. Gauze-wick drainage. Normal wound-healing.

Case V.—Acute appendicitis, abscess. Thomas H——, male, aged thirty-six years. No previous attack. Duration of present attack twenty days. General abdominal pain, localized after forty-eight hours in the right iliac fossa. Occasional vomiting. Has continued at work up to the present time.

Examination: Temperature, 101.2°; pulse, 96. A large tender mass in the right iliac fossa extending to the median line. Large thick-walled abscess cavity opened. Appendix not found. Gauze drainage. Intestinal concretion evacuated upon the third, and two more concretions upon the eighteenth day. Slight fecal fistula; closed spontaneously at the end of the month. Discharged cured at the end of two months.

Case VI.—Acute appendicitis, abscess. John M——, aged seventeen years. No previous attack. Four days, general abdominal pain, localized in the right iliac fossa after five hours. Vomiting; constipation. Abdomen distended, not rigid. Small tender mass in the right iliac fossa. Temperature, 100.4°; pulse, 100.

Abscess to the outer side and behind the colon containing a large concretion. Appendix one-half gangrenous; removed. No stricture demonstrable. Gauze drainage. Normal healing.

Case VII.—Acute gangrenous appendicitis. William W——, male, admitted February 3, 1899. No previous attack. Duration of present illness two weeks. Sudden onset. General abdominal pain, localized after twelve hours in the right iliac fossa. Constipation. Considerable tumor in the right iliac fossa. No rigidity. Temperature, 100.8°; pulse, 100.

Intermuscular incision. Gangrenous appendix removed with curette from the centre of a mass of granulation tissue lying rather high up to the outer side of the colon. Hole in colon, representing base of appendix, sutured. Normal wound-healing.

Case VIII.—Acute appendicitis, general septic peritonitis; death. Cornelius F——, male, aged thirty-nine years, admitted February 15, 1899. No previous attacks. Duration of present attack eight days. General abdominal pain and vomiting. Pain localized the second day in the right iliac fossa. Day before admission patient suddenly became much worse, vomiting growing severe, with intense general abdominal pain. Examination upon admission: temperature subnormal; pulse 130 and poor quality. General condition bad, abdomen distended and generally tender. Frequent vomiting.

Operation, February 15, 1899: Appendix not found; abdomen everywhere the site of general purulent peritonitis. Flushing of abdomen with hot saline solution; death in two hours.

Case IX.—Acute appendicitis, general septic peritonitis; death. Fred. E. M——, aged twenty-four years, male. No previous attacks. Five days before admission vomiting and general pain, localized after forty-eight hours in the region of the appendix; continued at work until the third day, when he went to bed.

On admission, large, stout man, profoundly septic in appearance. Temperature, 103½°; pulse, 108. Abdomen distended, tender, and tympanitic.

Operation: Appendix perforated and gangrenous, large abscess opened; the abdomen contained everywhere a thin sero-purulent fluid. Saline irrigation. Died septic on the second day with a temperature of 107°.

Case X.—Acute appendicitis, general purulent peritonitis; Cure. Michel F——, aged twenty-one years, admitted September 13, 1899. No previous attacks. Five days ago, general abdominal pain, localized

after twenty-four hours in the right iliac fossa, accompanied by vomiting. Since then and up to the time of admission the pain and tenderness had advanced to the left side of the abdomen. The entire abdomen tympanitic and tender. Temperature, 100.6°; pulse, 80.

Incision into either iliac region. Appendix swollen, perforated at the base. Entire lower three-fourths of the abdomen the seat of purulent peritonitis. Saline irrigation; glass-tube drainage into both iliac fossæ. Normal wound-healing. Discharged cured November 21st.

Case XI.—Acute gangrenous appendicitis, septic peritonitis, suppurative mesenteric adenitis, pyæmia. Susie W——, aged eighteen years, colored, admitted November 17, 1899. No previous attack. Thirty-six hours before admission, general abdominal pains, localized after six hours in the right iliac fossa, accompanied by tenderness and vomiting. Chill on the day of admission, tenderness and muscular rigidity marked on the right side. no tumor. Temperature, 101.8°; pulse, 92.

Operation on the day of admission: Moderate-sized collection of pus in the neighborhood of the appendix without limiting adhesions. Appendix found wrapped up in omentum, lying below the caput coli and slightly to the inner side. Meso-appendix and adhesions ligated; and omentum (one and one-half inches), after being separated from appendix, ligated in sections and end cut away. Appendix freed and opened one-fourth inch from caput coli; probed, and found pervious; cauterized, ligated with catgut, and cut away. Stump again cauterized. Saline irrigation, washing and sponging down into the pelvis, dry sponging into small intestine area and up toward the liver; in these directions it appears dry, the pus being only about the appendix and in the pelvis. Iodoform gauze packed to stump of appendix and into wound. Glass drainage tube with iodoform wick into pelvis. Sterile dressing and abdominal binder applied. Mucous membrane gangrenous throughout its whole length; three-fourths inch from base is a stricture, then a concretion three-eighths inch long, then a pin-hole perforation and complete gangrene. Chill followed by temperature of 105.2°. Signs of consolidation in right upper lobe, November 19th.

November 20th: Tube removed, wound quite clean; two chills, one in the morning, one in the afternoon. Upper lobe quite clear of signs of consolidation, lower right lobe has some bronchitis. Blood shows no malarial organisms. Chill in the morning and one in the afternoon of November 21st. Vomited four times during the day. Chill in the morning and one in the afternoon of November 22d. Vomited once. Chill in the morning, slight chill in the evening of November 23d. Sputum contains no tubercle bacilli. Chill in the morning, no pulmonary consolidation November 24th. Vomited once; general condition is unchanged, looks septic; chilly in the morning of November 26th. Urine negative; moderate tenderness in right hypochondrium and in right lumbar region; some resistance and muscular rigidity in regions of tenderness.

Second operation, November 27, 1899: Incision just below and parallel to right costal border, four inches in length. A mass of glands, ovoid in shape, two and one-half inches in long diameter, found behind hepatic angle of colon in front of the right kidney. Aspiration of foul putrid pus. Incision and removal of most of the mass. Packing. No other masses felt. Death ten days later with continued symptoms of septico-pyæmia, namely, chills, extremely high and remittent fever, delirium, stupor, and exhaustion. No autopsy.

Case XII.—Acute appendicitis, progressive fibrino-purulent peritonitis, persistent vomiting; death. Peter G——, aged eighteen years, admitted March 6, 1899. No previous attacks. Ten days ago he was seized with general abdominal pain, accompanied by a chill. He did not vomit. He continued at work during the two following days. Six days ago the pain became much more severe; he had another chill, and the pain localized in the right iliac fossa.

Examination: Poorly developed boy. Marked tenderness and rigidity over the lower part of the abdomen upon the right side. Temperature, 102.2°; pulse, 102.

Operation, March 7, 1899: Large abscess lying to the outer side of the colon together with a large collection of pus in the pelvis. The appendix was long, extended downward into the pelvis, and was perforated at its tip. Saline irrigation, followed by glass-tube drainage. The patient suffered from continued vomiting, which became fecal on the fifth day in spite of lavage. The bowels continued to move. There was no apparent extension of the peritonitis. The wound remained fairly clean and there was no rise of temperature above 101° until just before death, which occurred on the eleventh day after the operation, from exhaustion.

Case XIII.—Acute appendicitis, abscess; cure. Edward F——, aged twelve years, admitted February 24, 1899. No history of previous attacks. Two days ago general abdominal pains, accompanied by vomiting, located after six hours in the right iliac fossa. Next day a chill followed by an increase of pain and prostration. Constipated.

Examination: General abdominal tenderness, most marked in the right iliac fossa; together with muscular rigidity in the lower part of the right side of the abdomen. T., 100.8°; P., 116; R., 36.

Operation, February 24th: The appendix was found behind the colon wrapped in omentum, which formed the wall of an abscess of moderate size. Appendix strictured at proximal end and perforated at centre opposite a sharp kink. Pelvis free. Packing. Normal healing. Left hospital well.

Case XIV.—Acute appendicitis, abscess: cure. Thomas McK——, aged ten years, admitted March 3, 1898. No previous attacks. Nine days ago general abdominal pain, localized after twelve hours in right iliac fossa. Continued vomiting. No chill.

Examination: Well nourished; slight abdominal distention, everywhere tympanitic. Tenderness most marked over base of appendix. T., 101.4°; P., 120.

Operation, March 4, 1898: Colon adherent: large abscess evacuated. Appendix three inches long, strictured in two places, perforation at middle, gangrene of mucous membrane. Large secondary abscess filling pelvis. Salt irrigation, glass drainage, and yellow packing. On the tenth day a large lumbricoid worm emerged from the wound together with fecal matter. A large fecal fistula persisted.

January 13, 1899: Secondary operation revealed an opening into both large and small intestine rather deep in the pelvis. Curettage of cavity and packing. No attempt to close fistulæ.

April 30, 1899: Fecal fistulæ have closed spontaneously. Left hospital, well, May 17, 1899.

Case XV.—Acute appendicitis, abscess; cure. H. B——, male, aged twenty-three years, admitted April 9, 1899. One year ago had an attack of appendicitis lasting one week. Four months later another similar in character. On the day of admission he had general abdominal pain, located after two hours in the right iliac fossa, accompanied by vomiting.

Examination: Well-nourished man. Rigidity, pain, and tenderness over right iliac fossa. T., 101.8°; P., 108.

Operation twenty-four hours later: Abscess behind

colon. Appendix strictured near base and perforated at centre. Left hospital, well, May 22, 1899.

Case XVI.—Acute appendicitis, abscess; cure. James K——, aged eleven years, male, admitted May 1, 1899. No previous attacks. Seven days ago vomiting and general abdominal pains, localized after five hours in right iliac fossa. Diarrhœa. For past two days a mass has been noted in region of appendix.

Examination shows a well-nourished boy. Tender mass in right iliac fossa. T., 101.8°; P., 112.

Operation, May 1, 1899: Large abscess extending down into pelvis. Appendix bent sharply close to tip and perforated at that point. Glass-tube drainage into pelvis. Left hospital well.

Case XVII.—Acute appendicitis, abscess; cure. V. F——, male, admitted April 13, 1899. No previous attacks. Six weeks ago had pain in right iliac fossa. Kept at work for two weeks, after which he had chills at irregular intervals, accompanied by fever and sweating.

Examination: Well developed; large tender mass filling right iliac fossa. T., 102°; P., 116.

Operation April 14, 1899: Large abscess opened lying to outer side of colon and upward. Appendix not identified. Slow convalescence.

Case XVIII.—Acute appendicitis, abscess; cure. Patrick T——, aged twenty-seven years, admitted October 3, 1899. No previous attacks. Four days ago vomiting and general abdominal pain, located in right iliac fossa after twenty-four hours. General muscular rigidity.

Operation, October 4th: Abscess, gangrene of appendix, perforation, and concretion. Packing. Left hospital well.

Case XIX.—Recurrent appendicitis, abscess. George E——, aged six years, admitted May 17, 1899. Had two previous operations for appendicitis, at neither of which was appendix removed. A week ago another abscess appeared.

Operation, May 18th: Abscess opened; left hospital well.

Case XX.—Recurrent appendicitis, progressive fibrino-purulent peritonitis. William W——, aged nine years, admitted December 4, 1898.

Previous history: An attack of abdominal pain two months ago, lasting a few days.

Present illness: Five days ago sudden severe abdominal pain and vomiting. Pain chiefly in the left side of abdomen, low down.

Examination: T., 101°; P., 108. General condition poor. Abdomen distended, tense, tympanitic, and tender. Tenderness most marked in the left iliac region.

Operation, December 4, 1898: Incision in left iliac region. Peritoneum opened; small intestines agglutinated by recent adhesions, which being separated a moderate amount of pus escaped from among the coils of the small gut. Incision on right side. Similar adhesions toward median line, which being separated pus in moderate quantity escaped. A large congested appendix found dipping into pelvis and crossing to left side of belly. Appendix, stricture one-half inch from base, beyond that inflamed and distended with pus. Salt irrigation; packing of both wounds. Normal healing.

Case XXI.—Recurrent appendicitis, abscess. F. S———, male, aged forty-two years, admitted September 25, 1899. Had two previous attacks. Eight days ago present attack began. Pain and tenderness in right iliac fossa. Fever. Examination showed considerable tumor. Intermuscular operation, September 26, 1900. Abscess contained six ounces of pus. Appendix gangrenous; concretion: perforation at apex of appendix. Small fecal fistula still open after one month.

Case XXII.—Acute appendicitis, abscess; cure. Lilian D——, aged twenty-nine years, married, admitted November 26, 1899. No previous attacks. Three days ago vomiting and general abdominal pains, located after twenty-four hours in right iliac fossa. Sharp chill accompanying onset. Bowels open. Examination shows a strong healthy woman, abdomen distended and tympanitic. Rigidity, pain, and tenderness in right lower abdomen. T., 104°; P., 128; R., 30. Large abscess extending into pelvis. Appendix gangrenous and perforated, containing a large concretion and three small ones. Glass-tube drainage to pelvis. Temperature fell at once after operation. Wound-healing. Left hospital January 28, 1900.

Case XXIII.—Acute appendicitis, general peritonitis, septic diarrhœa. James R——, aged forty-two years, male, admitted January 22, 1900.

Previous history: Diarrhœa for three months, with emaciation. For past month has had continuous pain in lower abdomen, worse in the right side. Twenty-four hours ago sudden, very severe abdominal pain in lower part of abdomen and vomiting. Vomiting has continued. T., 101.6°; P., 100; R., 32. Whole abdomen tender, most marked below; muscular rigidity, free fluid in belly made out by percussion. Pulse weak. Patient much prostrated. Urine, albumin present, hyaline and granular casts.

Operation, January 22, 1900: Large amount of free pus in peritoneal cavity. Appendix perforated at tip. Free irrigation through glass tube. After operation wound discharged but little pus and continued to appear clean. Patient suffered from severe diarrhœa. No gastric disturbance until seventh day, when vomiting occurred. Patient passed but very little urine, containing albumin and casts. The temperature was but slightly elevated until the ninth day, when it rose to 101.8° just before death, which occurred from exhaustion. There was no reaccumulation in the belly.

Case XXIV.—Acute appendicitis, progressive purulent peritonitis. Marie K——, aged twenty-one years, admitted January 1, 1900. No previous attacks. Twenty-four hours ago, sudden severe abdominal pain, located after six hours in right iliac fossa: vomiting; marked chill.

Examination: T., 101.6°; P., 114. Abdomen moderately distended, tympanitic, and rigid. Tenderness everywhere marked, but most so over the base of the appendix.

Operation, January 1, 1900: Appendix gangrenous; no adhesions. Glass-tube irrigation of entire abdominal cavity. Abundant pus extending from the bottom of pelvis to the liver on the right side. Purulent fluid washed from left side of abdomen in moderate amount. Glass drainage tube to bottom of pelvis. Yellow gauze strip upward to liver. Wound-healing. Discharged well, February 6, 1900. Temperature fell at once after operation to 99.5°, and rose but twice to 100° thereafter, on the second and third days.

Case XXV.—General purulent peritonitis, acute appendicitis. George R——, aged eighteen years, admitted December 24, 1899. No previous attacks. Two days ago, sudden general abdominal pain, located in a few hours in right iliac fossa. Vomited several times; constipated.

Examination: T., 103°; P., 140; R., 24. No tumor, marked rigidity on right side; both sides of abdomen tender. Abdomen moderately distended and tympanitic.

Operation, December 24th: On opening of peritoneum free pus escaped from all directions. Appendix strictured at the base, mucous membrane gangrenous throughout, perforated near the base. A portion of gangrenous omentum removed with appendix. Pus appeared to be present in every portion of abdomen, with but little fibrin and few or no limiting adhesions.

Entire belly washed out with hot salt solution, and glass tube inserted. Glass drainage to bottom of pelvis, another upward toward liver. Temperature dropped at once from 103° to 99.6°, and pulse from 120 to 90. Temperature remained nearly normal thereafter. Bowels moved on third day after magnesium sulphate. Left hospital, well, February 9, 1900.

Case XXVI.—Acute appendicitis, progressive purulent peritonitis; cure. James G——, aged twenty-nine years, male, admitted January 6, 1900. No previous attacks. Chronic alcoholic. Abdominal discomfort and occasional vomiting for past two months. Last night sudden severe pain in lower abdomen, localized after a few hours in right iliac fossa, with vomiting.

Examination: Pain and tenderness in right lower half of abdomen, most marked in right side. No tumor. T., 104.9°; P. 110.

Operation, January 6, 1900: Free pus. Appendix gangrenous. Extent of peritoneal surface already infected large. Irrigation. Appendix large and strictured at base; distended with foul pus, gangrenous; no perforation. Left hospital, well, February 6, 1900.

Case XXVII.—Acute appendicitis, abscess; cure. Harold B——, aged sixteen years, male, admitted December 17, 1899. No previous attacks. Four days ago sudden severe peri-umbilical pain. Vomiting and fever. Pain located in right iliac fossa after twelve hours.

Examination: T., 104.2°; P., 120. Pain and rigidity and tenderness over right iliac fossa. Belly tympanitic.

Operation, December 17, 1899: Normal peritoneum opened; sacculated small abscess on outer side of colon containing two drachms of pus. Appendix perforated near base, behind a tight stricture. Distal extremity of appendix atrophied. Remainder inflamed and greatly thickened. Normal convalescence. Left hospital, well, February 17, 1900.

Case XXVIII.—Acute appendicitis, abscess; cure. Mary J——, aged twenty-three years, single, admitted November 21, 1900. No previous attack. Three days ago general abdominal pain, vomiting, chill next day. Pain and tenderness localized after forty-eight hours in right iliac fossa.

Examination: Large tender mass occupying whole of iliac fossa. T., 100.8°; P., 104.

Operation, November 21, 1900: Large localized abscess extending to bottom of pelvis. Appendix half gangrenous and perforated. Irrigation and yellow-gauze drainage to bottom of pelvis. Left hospital well, after convalescence delayed by a persistent sinus, which closed rapidly after administration of iodide of potassium and mercury.

Case XXIX.—Acute appendicitis, abscess; cure. William W——, aged seventeen years, admitted November 8, 1899.

Previous history: Numerous mild attacks during past two years.

Present illness: Two days ago general abdominal pain, located after twenty-four hours in right iliac fossa. Chill after twenty-four hours. Diarrhœa.

Examination: T., 102.6°; P., 96. Abdomen tympanitic. Rigidity marked on right side, and tenderness.

Operation, November 9th: Large circumscribed abscess extending to bottom of pelvis. Appendix strictured, containing concretion, partly gangrenous and perforated. Irrigation and packing. Wound-healing normal except for a temporary fecal fistula which closed spontaneously. Dismissed, well, January 7, 1900.

Case XXX.—Acute gangrenous appendicitis, abscess; cure. Julia C——, aged twenty-nine years, married, admitted March 22, 1900. No previous attacks. Twelve days before admission general abdominal pains, nausea, vomiting, and prostration. Pain localized after twenty-four hours in the right iliac fossa. A chill on the fifth day. Bowels moved daily. Pain in the region of the appendix continued to grow more severe until admission. Day before admission another chill.

Examination: There is a tender mass in the right iliac fossa the size of an orange. Firm and resistant, tympanitic. T., 102.2 ; P., 108.

Operation, March 23d; Large abscess opened to the inner side of and below the cæcum, extending well down into the pelvis. Appendix not found. Probably destroyed. Normal wound-healing. Temperature fell to normal soon after the operation. Left the hospital, well, May 8th.

Case XXXI.—Acute gangrenous appendicitis, abscess; cure. Maggie M——, aged twenty-two years, admitted April 2, 1900. No previous attacks. Five days ago severe pain in the right lumbar region, localized after twenty-four hours in the right iliac fossa. Bowels constipated.

Examination: Pain and tenderness and rigidity in the right iliac fossa. Temperature and pulse normal.

Operation, April 3d: Intermuscular incision. Cæcum buried in adhesions. Operation largely extra-peritoneal. Appendix partly gangrenous. Small circumscribed abscess. Gauze drainage; normal wound-healing; left the hospital, well, May 8th.

Case XXXII.—Acute gangrenous appendicitis; cure. Mamie R——, aged nineteen years, admitted March 27th. One mild attack of appendicitis three years ago. Four days ago general abdominal pain, localized after twelve hours in the right iliac fossa.

Examination: On the third day had a chill in the morning. Abdomen not distended. T., 100°; P., 90. Pain and tenderness in the right iliac fossa without rigidity. There is a tumor the size of a small orange to the inner side of the right anterior superior spine, exceedingly tender.

Operation, March 28, 1900: When the peritoneal cavity was opened the distal extremity of the greatly swollen appendix was found immediately beneath the abdominal wall, buried in recent adhesions and firmly attached to the inflamed cæcum. The appendix was long and bent upon itself. Its base was situated behind the cæcum. Removed in the ordinary way. There was no pus. The appendix was four inches in length; there was an impervious stricture at its middle, beyond which its canal was greatly dilated, filled with pus. The mucous membrane showed several gangrenous areas. Gauze drainage and partial suture of the wound. Normal wound-healing. Left the hospital well.

Case XXXIII.—Acute appendicitis, general purulent peritonitis. T. McS——, aged nine years, admitted December 2, 1899. No previous attacks. Four days ago he was suddenly seized with general abdominal pain, accompanied by vomiting, which was localized upon the following day in the right iliac fossa, although tenderness is said to have been marked over the whole abdomen. The vomiting has continued. The bowels have been constipated. On the day before admission his abdomen became distended. The distention has increased.

Examination: T., 102°; P., 128. He appears to be very ill. He is rather apathetic. His tongue is dry and brown. The abdomen is markedly distended, but not very tender except over the appendix region. There is slight muscular rigidity. No mass palpable. Enemata failed to move the bowels.

Operation, December 2, 1899: Incision over base of appendix. When the peritoneum was opened, pus in abundance gushed out under considerable tension. The pelvis was found full of pus and another large collection beneath the liver. Irrigation through glass tube showed abundant pus everywhere throughout the greater peritoneal cavity. There were slight but im-

perfect fibrinous adhesions here and there throughout the abdomen, which were broken down with the hand and with the tube. The appendix lay behind the caput coli; its mucous membrane was strictured in two places; between the strictures was a concretion, and the mucous membrane was gangrenous. Beyond the second stricture the appendix was thickened, perforated, and contained much pus. Prolonged irrigation of the entire peritoneal cavity with the Chamberlain tube and hot saline solution. The colon at the base of the appendix was infiltrated and in an unfavorable condition for suture. A purse-string suture was applied and mattress stitches were inserted over it. Large glass-tube drainage to the pelvis with iodoform-gauze wick. Packing at the base of the appendix. After the operation the patient vomited repeatedly. His temperature remained high, he was unconscious for several days, when improvement in his general condition became manifest. Upon the ninth day, the wound having become fairly clean, a fecal fistula was noted, which in spite of rest in bed persisted as a superficial sinus leading directly into the calibre of the gut until it was closed by suture four and one-half months later.

Case XXXIV.—General purulent peritonitis. Henry N——, aged seventeen years, admitted April 8, 1900. No previous attacks. Six days ago severe general abdominal pain, localized after three days in right iliac fossa, and accompanied by repeated vomiting. He has steadily grown worse, and upon admission to the hospital his temperature was 104.4°, pulse, 116. The abdomen is moderately distended, everywhere rigid and tender; the tenderness is, however, slightly more marked over the region of the appendix. The signs of free fluid in the abdominal cavity are fairly well marked. There is no circumscribed tumor.

Operation, April 8, 1900: Incision over base of appendix. Peritoneal cavity opened. Thin purulent fluid flowed out. Cæcum with the appendix pulled out of wound. Mesentery ligated; portion of mesentery between ligature and appendix divided. Purse-string suture around base of appendix. Appendix amputated one-half inch distal to stump. Stump cauterized. Glass-tube irrigation of every part of whole abdomen; large quantity of pus, with scarcely any limiting adhesions around it, was washed out from pelvis. More pus was obtained from the region above the appendix area, under the liver, and from the opposite side of the abdomen to the spleen. Glass tube inserted into pelvis and iodoform gauze packed to its bottom.

Pathology: Appendix three inches long, large perforation in distal end. Stricture about middle; a large concretion dropped out of it as soon as it was manipulated when found during the operation. Secondary abscess opened eleven days later through the left rectus muscle at the level of the umbilicus, after which the patient did well.

Case XXXV.—Frank D——, aged twenty-four years, admitted March 2d. No previous attack. Four days ago was seized with nausea and vomiting and general abdominal pains, which became localized in about six hours in the right iliac fossa. Symptoms have steadily grown worse up to admission, vomiting has continued.

Examination: T., 106.6°; P., 96. There is marked muscular rigidity of the right side of the abdomen over the base of the appendix. No definite tumor felt.

Operation: Incision over base of appendix. Small abscess opened behind the cæcum. Appendix strictured near the base, impermeable. Beyond this distended with thin pus, small perforation near the apex. Gauze drainage. Partial suture of the wound. Normal convalescence.

Case XXXVI.—James H——, aged twenty years, admitted April 9, 1900. No previous attacks. Became ill March 31st with sore throat, fever, chill, and general abdominal pain, followed by slight pain in right iliac fossa, which lasted only two or three hours. On April 3d pain in iliac fossa recurred and continued constantly until April 5th, when it suddenly became very severe. Bowels regular, no nausea or vomiting.

Examination: Well-nourished, strongly built man. Abdomen, upon pressure marked tenderness in lower umbilical and lumbar regions. Greatest tenderness in the right iliac region, most acute a little below site of base of appendix. Considerable rigidity over right iliac region. T., 103.6°; P., 100; R., 24.

Operation, April 10th: Distinct tumor felt in lumbar region, just above iliac crest. Incision in the lumbar region parallel to the border of the ribs. Peritoneal cavity opened. An abscess of considerable size was found situated behind and to the outer side of the colon. At the lower portion of the abscess the appendix was identified; it was very long and extended upward behind the colon, and was perforated at its tip. Length of appendix was six inches. The lesion appeared to be limited to its distal extremity. Suture of upper portion of wound. Normal convalescence.

Case XXXVII.—Chronic appendicitis, abscess, intestinal obstruction by bands, operation; recovery. Charles M——, aged twenty-nine years, admitted to Roosevelt Hospital January 8, 1900, with following history. During the past ten years he had three severe attacks of appendicitis. In the opinion of his attending physician, his last attack, which occurred about four months ago, was accompanied by severe pain, vomiting, fever, prostration, swelling of the abdomen, and obstinate constipation lasting five days. There was evident involvement of a considerable part of the peritoneum, diagnosticated as general peritonitis; he recovered from this attack incompletely, and during the past three months, while able to be about, has had constant discomfort in the region of the appendix, with tenderness upon pressure. His stomach has also given him some trouble, he has had numerous attacks of vomiting, his bowels have been fairly regular. He remained in the hospital under observation for a fortnight or twelve days, and was operated upon January 20th. During this time he had a slight evening rise of temperature on several occasions. There was a sense of increased resistance to be felt in the right iliac fossa, together with moderate tenderness on pressure.

Operation: Intermuscular incision. When the peritoneal cavity was opened the cæcum was found bound down firmly to the iliac fossa by old adhesions. When these were separated an abscess cavity was opened behind the cæcum containing only half a drachm of pus. Upon exploration the abscess cavity was found to communicate on the one hand with the open end of the partly destroyed appendix, one inch in length, and upon the other, distant an inch and a half from the base of the appendix, with the lumen of the large intestine, through an opening about one-third of an inch across. The appendix was amputated and inverted in the usual way, and the opening in the gut was sutured. A strand of gauze drainage; partial suture of the wound. The wound remained quite clean, but the patient began soon after the operation to vomit occasionally; his bowels were hard to move. His temperature was slightly elevated from time to time and he continued to suffer a certain amount of abdominal pain. Upon the thirteenth day following the operation a small movement of the bowels occurred, but the continued vomiting had greatly weakened the patient. Upon the fourteenth day symptoms of intestinal obstruction were well marked, the vomited

matters began to have a fecal character, his abdomen became distended, and nothing passed per rectum in spite of repeated enemata.

Operation on morning of the fifteenth day: Median incision. Coils of distended small intestine presented in the wound. Upon following them to the right the following conditions were noted. A coil of small intestine was firmly adherent to the ascending colon for an area of several inches in length along its inner surface. A second coil of small intestine adhered to the first coil in a similar manner. Passing transversely from the ascending colon toward the median line was a broad band of dense organized adhesions crossing the two coils of small intestine, to be attached to the mesentery near the middle line. The division and separation of these bands and adhesions was followed by severe bleeding, necessitating ligatures and pad pressure for its control. Further exploration showed also similar broad adhesions among the coils of small intestine situated in the pelvis. They were also spearated. Upon dividing the above-described fibrous bands the patency of the small gut was restored. These bands and adhesions were evidently the result of an ancient inflammatory process. Suture of the wound, with gauze-wick drainage. The patient made a slow but perfect recovery and left the hospital, well, early in March.

Case XXXVIII.—Acute appendicitis, progressive purulent peritonitis; recovery. H. M——, aged fifty-three years, male. A history of repeated attacks of abdominal pain accompanied by tenderness in the right iliac fossa, extending over a period of several years. None of them was severe enough to confine him to his bed. During the afternoon of April 16, 1899, he was suddenly seized with severe abdominal pain, localized after five hours in the right iliac fossa, at which time he had a chill accompanied by a rise of temperature to 103.5°. There was tenderness over the base of the appendix, involving also the entire right lower portion of the abdomen.

Operation was postponed by the patient for twelve hours. When the abdomen was opened thin pus escaped in considerable quantities. There were no limiting adhesions. The pelvis was filled with thin purulent fluid. The appendix was strictured about midway its length and perforated at its tip; it was amputated and the stump inverted. Irrigation of pelvis and neighborhood of appendix with hot saline solution; a glass-tube drainage to bottom of pelvis; packing to stump of appendix. Convalescence normal, except for the escape of a small amount of fecal matter from the stump of the appendix. The fistula closed after cauterization and packing.

Case XXXIX.—Acute appendicitis, general purulent peritonitis. Frank C——, aged eleven years, admitted April 12, 1900. No previous attacks. On April 6th, sick-headache accompanied by vomiting; no abdominal pain. April 9th, suddenly attacked with severe pain, localized from first in right iliac fossa. Vomited very freely for two days; no chill.

Examination: Tenderness almost entirely localized in right iliac fossa. A tumor, the size of a lemon, distinctly felt under anæsthesia close up under anterior superior spine of ilium. Considerable abdominal rigidity, most marked over right iliac fossa: but to some extent over whole of abdomen. T., 102.4°; P., 120; R., 24.

Operation, April 12th: Four-inch incision over the base of the appendix. Much pus filling the pelvis, found among the small intestines, apparently involving a large portion of the peritoneal cavity. The appendix lay behind the cæcum and was perforated. The entire abdominal cavity was irrigated with hot saline solution through a glass tube. Appendix removed. Glass-tube drainage to pelvis, iodoform packing to stump of appendix; partial suture of the wound. Normal convalescence.

Case XL.—Acute appendicitis, abscess; recovery. J. S——, aged twenty-three years. History of slow convalescence from typhoid fever six months before present illness, leaving him in a weak anæmic condition. Two weeks ago, never having had a previous attack, he was seized with vomiting and severe abdominal pain, localized after a few hours in the right iliac fossa. His condition since then has grown steadily worse, he has suffered from constant pain in the region of the appendix, has been confined to his bed, and has himself observed a tender mass slowly increasing in size in the region of the appendix. He has had a continued fever.

Examination shows the patient to be a rather poorly nourished individual; his face is distinctly septic in appearance. T., 103°; P., 100. The abdomen is not noticeably distended, but everywhere tympanitic. The right iliac fossa is occupied by a mass as large apparently as a fœtal head at term. Percussion note over the tumor is tympanitic. There is moderate muscular rigidity.

Operation, March 8, 1900: Incision four inches in length over tumor. Cæcum adherent to abdominal wall by fibrin. Large abscess extending to the bottom of pelvis was opened behind caput coli. It was walled off by dense adhesions from the general cavity of the belly. Appendix not found; it was apparently destroyed. Irrigation of hot saline solution through Chamberlain's tube. Iodoform-gauze packing. Normal convalescence.

The Parasitic Nature of Eczema.—P. G. Unna in making bacteriological studies of seventy-four cases of this disease was able to differentiate twenty-three types of coccus. These he arranges in five classes, according to their tendency to group formation. Those which do not show any such predilection, *i.e.*, the monads, form the first class, the dyads the second, tetrads the third, and octads and hekkaidekads the fourth and fifth. Of these twenty-three types twelve were found to give no results on inoculation into animals, four produced lesions somewhat impetiginous in nature but not at all resembling eczema, five types caused appearances strongly suspicious of the disease, and finally two gave all the characteristics typical of true eczema and are to be regarded as the producers of the disorder. One of these was found in over one-half of the cases examined and the other in only two instances, but then in pure culture. Carrying the investigation a step further and inoculating human beings it was found that absolutely typical eczematous lesions were produced by the two types under consideration. For these two the author proposes the names of Diclimactericus eczematis albus flavens and Monoclimactericus eczematis vivescens, while to a third strongly suspicious form he would apply the appellation Triclimactericus eczematis tenuis.—*Wiener klinische Rundschau*, September 16, 1900.

The Restoration of Function to Ankylosed Joints.—V. Chlumsky refers to the large percentage of failures attending efforts at cure of fixed articulations either by manipulation or open operation. The usual causes of this condition lie either in contractures of the soft parts or in bony or fibrous outgrowths of the articular surfaces. By massage it may be possible to restore the atrophied muscular tissues, and function may temporarily be improved by the non-bloody brisement forcé or by excision of the new growths, but the amelioration is apt to be evanescent, for the re-formation of the obstructing masses is not prevented. With the idea of imitating the false joints

sometimes occurring at the site of fractures owing to the interposition of muscle fibres, etc., between the separated ends, the author introduced foreign bodies of various sorts into the joints of dogs and rabbits after having resected portions of the articular surfaces. Thin plates of celluloid, silver, pewter, and rubber were used at first, but later it seemed preferable to employ substances capable of absorption, and decalcified bone, ivory, and magnesium were tried. The results in the animals experimented on were very encouraging and while no definite technique for the human subject can yet be formulated, further work will doubtless be productive of valuable therapeutic measures.—*Centralblatt für Chirurgie*, September 15, 1900.

Leontiasis Ossea.—W. H. Stephenson reports a case of this rare disease, which is characterized by an overgrowth or hyperostosis of all or some of the facial or cranial bones, without any concomitant affection of other parts of the body. The patient, a man of twenty-seven years, had first noticed a slight, hard, painless swelling on the left side of the lower jaw when thirteen years of age. About eighteen months ago a similar swelling had commenced on the right side of the lower jaw, and had gradually increased in size, but was not accompanied by any marked pain. During the last twelve months he had noticed that the bones of his nose had been growing larger, the nose had become increased in thickness and breadth, and the left nostril had become almost occluded. With the exception of neuralgic pains in the lower jaw of the left side, extending up to the temple, the patient had good health. The etiology of this disease is obscure. No treatment appears to be of any avail.—*The Medical Chronicle*, September, 1900.

The Leper Colony at Robben Island.—This island, Jonathan Hutchinson writes, is on the West coast of Africa, slightly north of Cape Town in Table Bay. He found that the lepers segregated there received almost no medical attention owing to the neglect of the medical officers, and that transportation thither was practically equivalent to imprisonment for life. He protests against such methods of caring for these unfortunates. His explanation and thoery of the origin and spread of leprosy at the Cape is the great amount of salted fish used. Much of this is sent to the interior, for it is light and easily carried. He believes that it is desirable that leper houses, comfortable hospitals and asylums, should be built. Lepers nearly always die, and that very soon, of tuberculosis and pneumonia. —*Medical Press and Circular*, September 26, 1900.

Disturbances of the Stomach in Relation to Diseases of the Chest.—J. M. Patton says that of diseases of the chest pulmonary tuberculosis occupies the most prominent place in connection with gastric disorders. Tuberculous ulceration in the stomach is rare compared with that of the intestines. This may be due to the germicidal action of the gastric juice, but more likely to the small amount of lymphoid tissue in the stomach and its deep situation. Gastric tuberculosis presents no definite symptoms. It occurs somewhat more frequently in males than in females. Clinically it is not of great importance, because death occurs from advanced tuberculosis of other organs, and because it is seldom diagnosticated though frequently suspected.—*Clinical Review*, October, 1900.

Flügge's Theory and its Application to Surgery. —Roberto Binaghi from the results of his researches concludes that the staphylococcus is the germ most frequently present in the air of surgical rooms. The more people usually found in these rooms, the greater the number of germs. They are found in greatest abundance in the lower strata of air. In operating-rooms the author has never found them before or during an operation but always after it. In clinic rooms they are present during and after the hours of treatment. In dispensaries and waiting-rooms staphylococci are constantly present. It would appear that they are infrequent when the temperature and pressure are low, as in February and March. The author thoroughly believes in Flügge's opinion that even when personal asepsis has been strictly observed, the mere motion of persons in an operating-room may, by causing light currents of air in which germs are suspended, cause infection of the wound. The number of persons in an operating-room should be reduced to the minimum. —*La Riforma Medica*, September 22 and 24, 1900.

Malarial Hæmoglobinuria.—James M. Parrott clinically and therapeutically divides the disease into two varieties, the asthenic and the sthenic. The latter is engrafted upon the more or less robust, though its more characteristic manifestations are preceded, as are the asthenic, by symptoms which are generally supposed to be those of ordinary malaria. The asthenic variety is engrafted upon one with a previous malarial cachexia. It occurs in those who are debilitated and weakened and whose excretory organs are functioning below normal because of certain organic pathological changes universally recognized as those of chronic malaria. The author gives in detail the symptoms of the two varieties. As to the treatment, the administration of quinine is a subject which admits of much discussion. This much should be said, that in sthenic cases seen before the beginning of the fourth day, quinine should be given. The alkaloid is not to be used in the asthenic cases except in very small doses, within the first few hours after the initial symptoms. Normal saline solutions properly used are of the utmost value. In sthenic cases the author sometimes bleeds from one arm and infuses into the other. This may be of especial service when suppression of urine threatens. The saline solution can be used by hypodermoclysis with good results. High rectal saline injections are very valuable. Whatever the form of treatment, nature must always be assisted to eliminate the poison, and the system supported until it can do so.—*The Carolina Medical Journal*, September, 1900.

Some General Considerations in the Treatment of Hysteria and Neurasthenia.—B. C. Loveland classifies his treatment for these disorders under five heads. 1. So far as possible correct errors of physique. Look for evidences of lithæmia, malaria, uterine disease, syphilis, cystitis, catarrhal disease in any part, eye-strain, dyspepsia, and constipation—any disease affecting the nutrition or any irritation which may in a reflex way cause nerve waste. 2. Institute healthful surroundings and healthful habits. Change of scene, abundance of fresh air, cheerfulness. 3. Hydrotherapeutics and calisthenics as equalizers of the circulation and natural nerve tonics. Both should be under supervision of the physician. 4. Correcting the mental attitude by properly and tactfully applied suggestion. By this is not meant hypnotism, but rather that we should set the patient to expect such and such results, the result being far more apt to follow than if such a state of expectancy is not induced. 5. Medicines. Strychnine is useful in these cases only in very small doses. Valerian, or pil. camphor, hyoscyamus, and valerian makes a good and harmless sedative. Bromides have their place. Phosphate of sodium is one of the best laxatives. Medicines alone never cure the cases, and careful attention should be given to physical and mental hygiene as most important factors in the treatment.—*Medicine*. October, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, November 3, 1900.

MOSQUITOS AND YELLOW FEVER.

DR. CHARLES J. FINLAY, of Havana, was the first to advance the proposition that the mosquito was the agent of transmission of yellow fever. It is now nearly twenty years since he denounced the insect as such in a Havana medical journal. Dr. L. Gererd, then surgeon-in-chief to the Panama Canal Company, came to the same conclusion, as the result of experiments performed upon himself, and made his opinions public in the *Canada Medical Record* in 1882. Others have from time to time declared their belief in the theory, but until Manson and Ross succeeded in demonstrating that a species of mosquito played a most prominent part in the etiology and propagation of the malarial infection, interest in the matter had become somewhat faint. However, the success of the British investigators in probing to a great extent the mystery of the dissemination of malaria, coupled with the serious outbreak of yellow fever in Havana, would seem to have stirred up the sanitary authorities of this country, and to have suggested to their minds that there might be something, after all, in Dr. Finlay's ideas.

But before going into the question of the work accomplished recently by the commission of United States army surgeons in Havana, it may be as well to epitomize Dr. Finlay's theory as stated in the MEDICAL RECORD, May 27, 1899. In the first instance he does not regard the mosquito as the intermediate host of yellow fever, but considers that the disease can be communicated directly by the mosquito to man. He argues by the process of exclusion that the malady is not infectious by direct contact, by the inhalation of the emanations of a sick person, or by the use of contaminated food or drink. Therefore Dr. Finlay contends that the yellow-fever germ is pathogenic only when introduced in a less trivial manner, probably by inoculation under the epidermis or even directly into a blood-vessel.

After the facts brought to light by Dr. T. H. Smith as regards the transmission of Texas fever by means of the cattle tick, this theory was to a certain extent modified so as to include the important circumstance that the faculty of transmitting the yellow-fever germ need not be limited to the parent insect, directly contaminated by stinging a yellow-fever patient, but may be likewise inherited by the next generation of mosquitos descended from the contaminated parent.

This, in short, was the situation with respect to the mosquito-yellow-fever question at the time when the United States commission began its investigations in Havana. The commission consisted of Dr. Reed, surgeon U.S.A., and Drs. James Carrol, A. Agramonte, and Jesse W. Lazear, acting assistant surgeons U.S.A.

The conclusions which they reached were made the subject of a paper read recently before the Public Health Association at its last meeting in Indianapolis, Ind. The studies were divided into two parts, the first of which dealt strictly with the bacteriology of the disease and the second with the rôle that the mosquito plays in its propagation.

Summarized the conclusions were as follows From the first part of the studies: (1) The blood taken during life from the general venous circulation, on various days of the disease, in eighteen cases of yellow fever successfully studied, has given negative results as regards the presence of bacillus icteroides (Sanarelli). (2) Cultures taken from the blood and organs of eleven yellow-fever cadavers have also proved negative as regards the presence of this bacillus. (3) Bacillus icteroides (Sanarelli) stands in no causative relation to yellow fever, but when present should be considered as a secondary invader in this disease. The deductions drawn from the second part of the studies read thus: "The mosquito serves as the intermediate host for the parasite of yellow fever, and it is highly probable that the disease is only propagated through the bite of this insect."

While the conclusions relating to the Sanarelli bacillus make a part of the record they cannot be regarded as in any way convincing when we take into account the mass of testimony to the contrary. At best the observations were very limited in extent and can carry only a proportionate amount of weight to the contrary view of a very generally accepted opinion.

The conclusions of the second part are far more suggestive and interesting, and were arrived at as the result of eleven experiments upon non-immune human subjects who allowed themselves to be bitten by mosquitos which had been previously fed upon yellow-fever patients. Of these experiments nine results were negative and two positive. In one of these two positive cases, other sources of infection were, it is stated, clearly excluded: The offending mosquito, Culex fasciatus Fabr., was also isolated.

The commission is to be warmly congratulated upon the work is has done thus far, but is it not claiming rather too much to assert that "it is highly probable that the disease is only propagated through the bite of the mosquito," especially when the fact is taken into consideration that the case mentioned above is the only one in which a typical attack of yellow fever has followed the bite of an infected mosquito, all other sources of infection having been excluded? The theory, of course, is identical with that of placing upon mosquitos the onus of spreading malaria, and the Culex fasciatus Fabr. may be proved as much of a sinner as its brother the Anopheles.

In the mean time, however, it will be judicious to "hasten slowly," as well as to bear in mind that yellow fever differs widely in its mode of outbreak and

in other important characteristics from malarial fever, more resembling in many respects the bubonic plague. This much concerning yellow fever is agreed upon by the majority of investigators: That the disease is not contagious in the strict sense of the word, but that its micro-organisms will infect certain circumscribed areas or zones, conveyed thither perhaps by fomites; that maritime commerce has hitherto been the principal means of its dissemination; that it is conveyed neither by food nor by water, but by aerial diffusion; that soil has no apparent influence on its origin or spread, but that climate undoubtedly has.

Dr. A. H. Doty, health officer of the port of New York, in an article in the *North American Review*, 1898, sagely remarks: "Although there may be some doubt as to what are the climatic conditions necessary to propagate yellow fever, there is no difference of opinion as to what are the local requirements. I refer to filth and defective drainage. There is no city in the world to-day where yellow fever is epidemic, which does not afford substantial proof of this truth."

Inspector-General Turnbull, R.N., read a paper on the subject of yellow fever at the recent meeting of the British Medical Association, in which he contended that environment was the immediate cause of yellow fever, and that whenever improved sanitation supplanted a wholly unsanitary state, yellow fever disappeared. It is true that there are no facts known with regard to yellow fever which render the proposition that the malady is spread by the mosquito quite tenable; on the contrary, many appear to be unfavorable to such a theory. In this connection it must be remembered that yellow fever in a given district is not always coincident with the existence of mosquitos. In the epidemic of Jacksonville in 1888, the mosquito, while present, was by no means in such number as to constitute a pest. McHenry, Miss., in 1897, was almost free from the insect, as was likewise the case in some of the stricken districts of Florida in 1888. Although this does not absolutely disprove the new theory, the spread of the disease in every instance was duly explained by fomites in the nature of bedding or wearing-apparel packed in an epidemic centre.

In the absence of any new facts bearing on either side of the question at issue, therefore, it is quite evident at this stage of the argument that the whole matter requires a great deal more sifting before a definite opinion can be expressed. In conclusion we wish to express our unstinted admiration of the noble and unselfish conduct of Drs. Lazear and Carrol in offering themselves as subjects for experiment for the furtherance of science. The first-named fell a martyr to his devotion, but his name will be duly inscribed on the roll of fame and reverently remembered as an enthusiast who risked and lost his life that humanity at large might profit thereby.

Two Sets of Triplets.—Two sisters, twins, married two brothers, also twins, less than a year ago in Huntington, W. Va. On the same afternoon last week each sister gave birth to triplets.

THE CORRELATION BETWEEN SEXUAL FUNCTION, INSANITY, AND CRIME.

It is probable that no part of the body is without relation to all other parts, and that disease of any organ will not be without influence upon the remaining organs. Such a conception is justifiable from a knowledge of the interrelation of function and from a belief in the production of internal secretions. The symptoms that arise in the sequence of removal of glandular structures believed to possess such internal secretions are principally referable to the nervous system, and they have been most conspicuously observed in connection with disease or destruction of, or operation upon, the thyroid gland, the uterus and ovaries, and the pancreas. Great importance—too much, we are inclined to think—has always been attached to the onset and the cessation of, as well as abnormalities in, the processes of ovulation and menstruation in the development of various morbid manifestations, although it does not seem impossible that, in one predisposed to mental derangement, such conditions may act as the exciting cause. At the conclusion of a paper on the correlation between sexual function, insanity, and crime, read before the section of psychology at the recent meeting of the British Medical Association, Macnaughton-Jones (*British Medical Journal*, September 22, 1900, p. 789) expressed the belief that functional disorders of ovulation are frequently attended with mental aberration, and in a proportion of cases originate the mental disturbance. The same statement is applicable to disorders of ovulation dependent upon pathological causes. He held that, in the great majority of such cases, the disturbance is of a neurasthenic character and is associated with various visceral or other neuroses, while in only a small proportion does the alienation assume so grave a type as melancholia, mania, or dementia. In his opinion, when in an insane person ovulation and its external manifestation, the menstrual discharge, are erratic or absent, the erraticism or absence may be a consequence of the general and insane condition and not a causal factor in its production; but under any circumstances such abnormal menstruation appears to have an aggravating effect on the insanity, and there is sufficient evidence to support the view that when such irregularity—especially if it be due to a pathological cause—exists, it should be treated therapeutically or by operative measures. It was thought that the question of a gynæcological examination of an insane woman must be a matter for the discretion of the psychologist, influenced by the gynæcological view as to its expediency from the signs and symptoms present in the sexual organs. For many reasons this is not advisable as a universal practice with our present knowledge. It was pointed out that sufficient evidence is now advanced to justify the removal of the adnexa or the uterus in insane women when there are gross lesions of the former or tumors of the latter. Here again such operation must be advised in accordance with the psychological condition of the patient and the type of her insanity. The conclusion was reached from a mass of evidence, including some of the largest experi-

ences in Europe, Canada, and America, that in healthfully minded women who suffer from diseases of the genitalia there is no special risk of post-operative insanity; on the other hand, if there be a psychopathic predisposition that has existed prior to and independently of the sexual disease, there is in such cases a larger percentage of post-operative mental disturbance than follows other operations. In such women the prudence of a radical operation may have to be carefully discussed. The post-operative mental effect does not appear generally to be of a serious or permanent nature. It may be generally affirmed that when mental disease of a graver type follows upon sexual disorder, there has been in the woman affected an underlying and often unrecognized psychopathic predisposition; the disorder of menstruation or the disease in the genitalia completing the chain of the vicious circle needful for the final manifestation of the mental condition. Finally the contention was made that the relation of aberrant sexual function or disorder of menstruation to any criminal act ought to be taken into consideration in determining the responsibility of the woman.

News of the Week.

More Army Surgeons Wanted.—In his annual report to the Secretary of War, Surgeon-General Sternberg says that the present medical staff, consisting of one hundred and ninety-two surgeons, is insufficient for the needs of the service in view of the large number of coast-defence stations and the troops operating in Cuba, Porto Rico, Hawaii, and the Philippines. The contract surgeons, Dr. Sternberg says, have rendered excellent service, but the situation demands a permanent increase in the number of regularly commissioned surgeons.

New Site for the Harvard Medical School.—The old Francis estate in Brookline, Mass., has been purchased, and is now held in trust as the proposed future site of the Harvard Medical School, and the allied departments of veterinary medicine and dentistry will also be located on the recently acquired land. The school, during the comparatively short period of its residence in the present building, has outgrown its accommodation, and the land furthermore is desirable for the future use of the Boston Public Library, which is already feeling the need for more space. An appropriation for the School of Comparative Medicine has already been made from the H. L. Pierce bequest to Harvard University. Space is furthermore provided for a possible University Hospital.—*Boston Medical and Surgical Journal.*

The Descent of Man.—A despatch to *The Sun* from Berlin states that, at the recent congress of German anthropologists at Halle, Professor Klaatsch, of Heidelberg, read a paper contending that the direct descent of man from apes was no longer maintainable. His conclusion was based on the construction of the biceps muscle of the thigh. He contended that it was a mistake to regard man as the most perfectly developed mammal in all respects. His limbs and teeth do not show any high degree of development, and he is superior to other animals only in his extraordinary brain development.

A Falling Birth Rate in Berlin.—It is not in France only that the birth rate is declining, for some recently published official statistics show a continuous decrease in the Berlin birth rate, which is now only 29 in 1,000. The number of children born during the period covered by the statistics was 450,000, which, if the birth rate had been the same as in the whole of Prussia, would be 700,000.

Students of Medicine in Italy.—During the session of 1899–1900 there were 6,648 students in attendance at the medical schools of the numerous Italian universities, being distributed as follows: Naples, 2,009; Turin, 783; Rome, 530; Bologna, 504; Pavia, 496; Genoa, 358; Padua, 309; Palermo, 270; Florence, 260; Pisa, 218; Modena, 152; Catania, 167; Parma, 175; Messina, 128; Siena, 81; Cagliari, 75; Sassari, 54; Camerino, 35; Perugia, 29; Ferrara, 15.

Raw-Meat Cure of Tuberculosis.—An institution was opened a few months ago in Belgium for the purpose of carrying out Richet's alleged "cure" for tuberculosis by an exclusive raw-meat diet. After a trial of not more than three months, the experiment has been abandoned, those in charge of the hospital asserting that there was no efficacy whatever in the method.

An American Nuisance in London.—"Zionist" Dowie has been lecturing in London and several hundred medical students have been silly enough to advertise him by attending his meetings and creating a disturbance. At one of the meetings he told the noisy students that they had been incited to make a disturbance by their teachers who feared that faith healing would ruin their practice. At the next meeting the students assembled in greater force, and shouted, sang songs, blew trumpets and whistles, sounded rattles, and caused a great uproar. Dowie summoned the police, who ejected three of the disturbers. This incensed their comrades, who stormed the platform. Dowie bolted through a side door. Fifty of his supporters met the rush and a fierce fight ensued, in which sticks were used. The police eventually cleared the hall.

A Convalescent Hospital in the Philippines.—It is stated in Washington that plans are under consideration for the establishment of a first-class sanatorium within convenient distance of Manila, in order to place that city on the same footing in that respect as other large cities in the Orient. A sanatorium is regarded as necessary for dwellers in the tropics. The place selected is Beago de la Trinidad, about four thousand seven hundred feet above sea level, with a salubrious climate, the thermometer never rising above 75° in the daytime and the nights being cool and exhilarating.

New York State Association of Railway Surgeons.—The annual meeting of this association will be held at the Academy of Medicine, New York City,

on Thursday, November 15, 1900, under the presidency of Dr. J. L. Eddy, of Olean. The secretary is Dr. C. B. Herrick, of Troy.

The Philadelphia Medical Club on October 26th tendered a reception to Dr. Maurice H. Richardson, of Boston.

Dr. S. Baruch, of this city, has been awarded a silver medal and a diploma at the Paris Exposition for his plates and statistics showing work done in providing free cleansing baths for the poor. In this exhibit the aim was to show the sanitarians of the world that we have solved in America the problem of free cleansing baths, which have been in full operation in Buffalo and Chicago for several years. There are no other free cleansing baths in the world.

The Mississippi Valley Medical Association will hold its next annual meeting at Put-in Bay, Ohio, on September 10, 11, and 12, 1901. The officers for this meeting will be: *President*, Dr. A. H. Cordier, of Kansas City, Mo.; *Vice-Presidents*, Drs. C. F. McGahan, of Aiken, S. C., Charles L. Minor, of Asheville, N. C.; *Secretary*, Dr. Henry E. Tuley, of Louisville, Ky; *Treasurer*, Dr. Dudley S. Reynolds, of Louisville, Ky.; *Chairman of Committee of Arrangements*, Dr. J. C. Culbertson, of Cincinnat.

The Southern Surgical and Gynæcological Association.—The thirteenth annual meeting of this association will be held in Atlanta, Ga., on November 13th, 14th, and 15th, under the presidency of Dr. A. M. Cartledge, of Louisville, Ky. The secretary is Dr. W. E. B. Davis, of Birmingham, Ala. The programme contains forty titles of papers to be read.

Dr. Bulkley's Lectures on Diseases of the Skin.—The third course of clinical lectures on diseases of the skin will be given by Dr. L. Duncan Bulkley in the out-patient hall of the New York Skin and Cancer Hospital, Second Avenue and Nineteenth Street, on Wednesday afternoons, commencing November 7th. These lectures, the previous courses of which have been largely attended, are free to all members of the medical profession.

Philadelphia Hospital.—The Council's committee on charities and correction has recommended favorably the appropriation of $130,000 for the erection of new buildings as additions to the Philadelphia Hospital, as follows: $50,000 for enlarging the buildings of the insane department; $35,000 for erecting a children's hospital; $10,000 for erecting a maternity house; and $35,000 for erecting a building for the treatment of infectious diseases.

Pan-American Medical Congress.—The third Pan-American Medical Congress will be held, as already announced, in Havana on December 26th, 27th, 28th, and 29th. There will be three general sessions. At the opening session in the Marti Theatre there will be present, besides the congressists, members of various scientific bodies and other invited guests. The report of the secretary-general will be read, and there will follow an address of welcome by the president of the congress. There will also be an address by Governor Wood, and two scientific addresses. At the second general session there will be four scientific addresses, one by a Cuban physician. At the closing session the report of the treasurer will be read, one scientific address will be presented, brief remarks will be made by the representatives of several countries, and the secretary-general will announce the place chosen for holding the fourth congress. The section meetings will be held daily from 8 to 11 A.M. and from 3 to 5 P.M. The dues for members of the congress will be $10 in gold. Each member who purposes reading a paper is requested to send to the secretary an abstract, not exceeding three hundred words, not later than November 15th. It is thought that about one thousand physicians will attend. Three hundred of the delegates will be Cubans. A large number will come from Mexico, travelling on a Mexican warship. Many American physicians are expected. The executive committee consists of Dr. Juán Santos Fernandez, president; Gustavo Lopez, vice-president; Tomàs V. Coronado, secretary; Enrique Acosta, treasurer; and Vicente K. Valdés, José I. Torralbas, and Edwardo F. Pla. The address of the secretary is Prado, 105, Havana, Cuba.

Pathological Society of Philadelphia.—At a stated meeting held October 25th, Dr. Simon presented for Dr. Hidago Nagouchi a communication on the "Influence of Cold upon the Plague Bacillus," based upon observations made during midwinter in northern China. It was found that even quite low temperatures had little injurious influence upon the micro-organisms, which are much more susceptible to elevations above the optimum. Dr. James F. Schamberg read a paper entitled "Pathology of the Skin in Scarlet Fever," accompanied by an exhibition of sections and photographs illustrative of the lesions. Dr. L. N. Boston demonstrated a forceps for holding microscopic slides. Dr. A. O. J. Kelly exhibited organs from a case of acute phosphorus poisoning, occurring in a young child that had swallowed about a dozen match-heads. The viscera, the skin, and the mucous membranes were the seat of small hemorrhages, and the liver was enlarged and fatty. Dr. A. A. Eshner exhibited a specimen of cerebral hemorrhage, an extensive extravasation of blood having taken place into the basal ganglia and being visible from the lateral ventricle. Dr. F. A. Packard exhibited anthracotic lungs from a miner who had presented symptoms of pulmonary gangrene, and relief from which appeared urgently indicated. An incision into the lung was made and drainage provided for, but although the local condition improved, except for the development of cutaneous emphysema, the patient failed to rally and apparently died from toxæmia and exhaustion. Post-mortem examination disclosed a bronchiectatic cavity at the apex of the right lung, with a gangrenous cavity in the lower lobe.

Philadelphia County Medical Society.—At a stated meeting held October 24th, Dr. Arthur Dare demonstrated a new hæmoglobinometer, in which a thin layer of undiluted blood is compared with corresponding standardized color discs. Dr. Henry W. Stelwagon gave a brief account of a visit to Pro-

fessor Finsen's light institute at Copenhagen, describing the treatment of lupus by means of natural and artificial light concentrated upon the disease foci with the aid of lenses. Daily exposures for an hour are made, but the treatment must be continued for a long time. It is questionable if the results are better than they would be if the same attention were given to details in the application of other remedial measures. Dr. Augustus A. Eshner reported some anomalous cases of typhoid fever, one unusually severe, one extremely mild, two with hemorrhagic tendencies, one possibly unattended with intestinal ulceration, one simulating miliary tuberculosis, one with intercurrent malarial fever in a puerperal woman, one associated with pulmonary tuberculosis and pneumonia, and one associated with syphilis and pulmonary tuberculosis. Dr. Norman B. Gwynn read a paper on "The Presence of Typhoid Bacilli in the Urine, and the Disinfection of Such Urine." After reference to the relative frequency with which typhoid bacilli are found in the urine in cases of typhoid fever, experiments were detailed showing that mercuric chloride and chlorinated soda are the best disinfectants for the urine after it is voided. Ammonium formaldehyde may be employed for the purposes of sterilizing the urine in the genito-urinary tract.

Insanity among the Troops in the Philippines.—In his annual report to the Secretary of War, Surgeon-General Sternberg says regarding insanity among the troops: "In the army, regulars and volunteers, during the calendar years 1898 and 1899, there were reported on the monthly reports of sick and wounded 347 cases of insanity, and 202 of these cases, or 58.2 per cent., were committed to the government hospital for the insane. One hundred and thirty-five cases, or 66.7 per cent. of the commitments, recovered in an average period of 3.9 months, 13 were improved, 6 died, and 48 remained unimproved. Ninety-six of the 347 cases were reported on the monthly reports of troops serving in the Pacific islands, and 32 of these, or 33.3 per cent., were sent to the government hospital for the insane. Seventeen cases, or 53.1 per cent. of those committed, recovered in an average of 3.6 months, 2 were improved, 2 died, and 11 remained not improved."

Suing for Expert Fees.—Dr. R. A. Witthaus, whose bill for $18,550 for examining the stomachs of Mrs. Katherine J. Adams and Henry C. Barnett, under direction of the district attorney, in the Molineux case, was not paid on account of the small amount in the sinking-fund, will sue the city to recover the full amount of his bill.

Dr. Leopold Javal, the eminent French ophthalmologist, who has just been made officer of the Legion of Honor, recently lost his sight as the result of glaucoma. He began his career as a mining engineer, but having undertaken the translation of Helmholtz's "Optical Physiology," he was so much interested that he studied medicine and took up ophthalmology as a specialty. Some years ago he was elected member of the Chamber of Deputies, and was instrumental in passing the "Seven Children Law," which exempts from taxation the parents of families of not less than that number. He now devotes his attention to the improvement of the means of enabling the blind to read and write.—*The Medical Press and Circular.*

The Flushing Hospital.—The trustees of this hospital have issued a statement to the effect that the institution may be obliged to close its doors because of lack of funds. The city gives the hospital $6,000 and it has an income of $3,000 from pay patients, but the expenses are about $14,000.

Obituary Notes.—Dr. Moses C. White, of New Haven, Conn., died at his home in that city on October 24th, at the age of eighty-one years. He was born in Paris, Oneida Co., N. Y. He first studied for the ministry and was for several years a missionary in China. He then studied medicine and was graduated from the Yale Medical School in 1854. He was for many years pathologist to the State Hospital, and was a member of the faculty of the Yale Medical School. Two sons, one a physician, Dr. Caryl S. White, survive him.

Dr. William Arthur Zabriskie died at his home in this city on October 27th from fracture of the skull received by falling and striking his head on the sidewalk. He was forty-two years of age, and was graduated from the College of Physicians and Surgeons in 1882.

Dr. William J. Nelson, of Middletown, N. Y., died on October 26th at the age of forty years. His death was indirectly due to an injury to the spine received while a student at college, when a fellow-student cut a rope from the hammock in which Dr. Nelson was swinging, throwing him to the ground.

Dr. Edward Addison Hervey, of Rossville, Borough of Richmond, died on October 26th in his seventy-seventh year. He was born in South Durham, N. Y., on January 24, 1824, and was graduated from the University Medical College in this city in the class of 1859, receiving the Elliot prize for proficiency in anatomy.

Dr. Edward Robinson Squibb, of Brooklyn, died on October 26th of cardiac trouble after a short illness, at the age of eighty-one years. He was born in Wilmington, Del., and was graduated from the Jefferson Medical College, Philadelphia, in 1844. He entered the naval medical service, and was surgeon in charge of the Brooklyn navy yard when the Civil War began. About this time he resigned from the navy and became a manufacturing chemist. He retired from active business about fifteen years ago. He was a member of the American Medical Association, the New York State Medical Association, the Kings County Medical Society, the Metropolitan Museum of Art, and the Philosophical Society of Philadelphia. A widow, daughter, and two sons, one of whom is Dr. Edward H. Squibb, of Brooklyn, survive him.

Dr. Laurence Turnbull died at Philadelphia on October 24th, at the age of seventy-nine years. He was a native of Scotland, coming to this country at the age of twelve years. He was a graduate in pharmacy, and in 1845 was graduated from Jefferson Medical College. He served as resident physician in the Philadelphia Hospital, and was for thirty years prior to

1887 one of the physicians to the Western Clinical Infirmary and Howard Hospital, subsequently becoming a manager of this institution. He was in 1877 made aural surgeon to Jefferson Medical College Hospital. He was the first surgeon in the United States to trephine the mastoid for ear disease. He was the author of a "Manual of Anæsthetic Agents and their Employment in the Treatment of Disease," and of a "Clinical Manual of Diseases of the Ear."

Dr. George A. Muehleck died at Philadelphia on October 25th of typhoid fever, at the age of forty years. He was a graduate in classics of the University of Tübingen and in medicine of the University of Heidelberg. He was a member of numerous medical societies, and pathologist to St. Agnes Hospital.

Dr. Alexander H. Johnson, of Newark, N. J., died suddenly at Indianapolis while in attendance upon the meeting of the American Public Health Association. He was a member of the Newark board of health.

Progress of Medical Science.

Boston Medical and Surgical Journal, October 25, 1900.

Physiological Dilatation and the Mitral Sphincter as Factors in Functional and Organic Disturbances of the Heart.—Morton Prince says that whenever the heart is obliged to do an increased amount of work, whether this be due to increased stimulation of the heart or to increase of the resistance against which the blood is thrown, the heart physiologically dilates. This dilatation within normal limits may be so great that the volume of the blood thrown out at each contraction may be trebled or quadrupled. At the end of systole the heart may be larger than it was before at the end of diastole. The sphincters may be so dilated that the valves cannot close the auriculo-ventricular orifices, and thus physiological regurgitation may result. Normally this is observed under nervous excitement and severe physical exercise. The same law of necessity applies to diseased hearts as to healthy hearts, and, for example, the dilatation observed in aortic stenosis may be physiological rather than pathological. In general systemic conditions, such as the febrile diseases, anæmia, Bright's disease, etc., the dilatation and regurgitation are of the same sort, due either to an absolute increase of resistance or to a relative increase; in the latter case because of a weakened heart working against normal resistance. Unless this is recognized there is great danger of confusing this purely physiological condition, which probably exists in a great many such cases with serious cardiac disease, and in consequence giving an unfavorable prognosis.

Congenital Dislocation of the Hip Joint.—E. H. Bradford, discussing the various procedures for the cure of this condition, says that it is manifest that for the best result as little injury as possible should be done to the tissues. Little is inflicted if the following procedure be carried out: An incision is made along the outer and anterior edge of the femur, reaching from above the greater trochanter to two inches below the lesser trochanter. The upper portion should be curved slightly upward so as to uncover the head and neck of the dislocated femur. The tensor vaginæ and gluteus medius muscles are separated. When the femur is reached, the femoral insertion of the rectus is pushed aside, and the attachments of the psoas and iliacus are pushed away by a periosteum elevator. The capsule is then opened and cut across, first on the head, in the line of the axis of the neck, and then from the neck downward toward the acetabulum in front and behind. The finger is inserted, the acetabulum exposed, and the size of the capsular neck estimated. The capsular insertion on the femur is then entirely cut away, as well as the ligamentum teres, and the head of the femur pulled aside. This should be placed in the acetabulum and the incised capsule stretched around the neck and secured by catgut sutures to the cut tissues around the neck, or to the opposing parts of the cut capsules.

A Case of Contracting Scar of the Palm of the Hand Remedied by a Flap from the Abdomen.—F. M. Briggs reports a case in which, following laceration and burning, the entire palmar surface of a woman's left hand was composed of cicatrix. The author describes the operation by means of which a new palm was created by a flap from the abdomen. The result is wholly satisfactory. The skin of the new palm is soft and pliable, and is fully doing its work. The operation not only has substituted good skin for weak cicatrix, but has restored the function of the useless hand. Taking such a flap from the abdominal wall insures good nutrition, provided a long base line is left for the pedicle, and the skin grafted in the manner described makes an excellent substitute for the original skin. The author believes this to be the first case in which this particular method of plastic work has ever been attempted in the treatment of such a defect.

Medical News, October 27, 1900.

Repairing the Abdominal Wall in Ventral Hernia.—Carl Beck describes his operation on a ventral hernia in the scar of an appendicular incision. The scar was incised and the peritoneum exposed. After the few adhesions were disposed of and the different abdominal layers carefully denuded, an approximation of the muscular tissues was found to be impossible. Consequently, the rectus was incised alongside its internal margin to the extent of nearly half its thickness. Two transverse incisions connecting the outer and inner margins of the muscle and extending down the substance of the muscle to the same extent, the lower one being as near Poupart's ligament as possible, and the other one below the umbilicus, completed the outlining of the flap, which was carefully lifted. Beginning at the internal marking of the incision, the upper layer of fibres of the rectus was also divided, until the flap so formed could be lifted near the outer margin, with which it remained connected in the manner of a hinge. The reverted flap was now fastened to the muscular remnant with iodoform-silk sutures. The ties uniting the fascia consisted of formalin-catgut, which was also selected for the subcutaneous suture. Four relaxation sutures were applied through the skin three-quarters of an inch from the wound-margin, so that there was no direct contact with the wound-line. Recovery was uninterrupted. Two months after the operation no protrusion occurred while the intra-abdominal pressure was increased by the efforts of coughing.

A Plea for More Frequent Avoidance of Exsection of the Ovaries in Connection with Operations upon Diseased Tubes.—Philander A. Harris states that less than three years ago he abandoned the routine practice of removing the ovaries with their diseased tubes. He spares as much ovarian tissue as possible. He remembers but two instances in which a surgical menopause followed double-tube amputation or excision during this time. To the woman of respectability, the knowledge that she is not as other women are will be a strong factor in causing her unhappiness. The writer believes that sufficient ovarian stroma may be saved to maintain menstruation and ovulation in at least ninety per cent. of all the bilateral tubal amputations and exsections for the so-called purely inflammatory lesions of and primarily in the tubes, and that a cure of pelvic pains does not depend on the removal of the ovaries, but on a removal of the disease from the Fallopian and uterine sinuses. A woman with sufficient ovarian stroma for menstruation and ovulation, but with one tube exsected and the other amputated, is not likely to conceive. Still pregnancy is possible in her case.

New York Medical Journal, October 27, 1900.

"Thimbles" for Massage and Stripping of the Seminal Vesicles.—J. R. Eastman thus describes an instrument he has devised and the method of its employment: The thimbles imitate in shape the slightly bent finger, and are of nickel-plated brass three inches long, thus adding about an inch and three-quarters to the length of the massaging fingers. The distal end is broadened to the width of an inch and swells rather flatly in its full breadth from the palmar surface. The patient stands with knees straight and body slightly bent forward at right angles, and the instrument is introduced with the palmar surface of the entering finger upward, the concavity of the thimble toward the

sacrum. When the instrument has been gently introduced as far as possible, the perineal muscles having become relaxed, the finger and thimble should be so turned that the palmar surface of the finger faces the bladder. The broadened and projecting anterior face of the distal end of the thimble will now rest high up on the body of the vesicle or above it. While gentle pressure is maintained, the thimble should be drawn slowly forward along the line of the vesicle with counter-pressure over the abdomen. By passing the instrument successively backward and forward, the vesicle may be thoroughly emptied.

Disturbances of Gastric Motility and their Significance.—Eleven cases of gastric disease are briefly reported by A. Macfarlane, in order to emphasize the importance of motor disturbances; three are cases of carcinoma, one involving the pylorus, two affecting the lesser curvature; three are cases of pyloric stenosis after ulcer; four are cases of gastro-neuroses; and one is a case of perigastritis with pyloric stenosis due to carcinoma. If reliance had been placed upon the chemical examination alone, it would have been impossible to make a diagnosis, because the same variations in the secretion of hydrochloric acid were present equally in the carcinomata and in the neuroses. When the motility is considered, it is seen that all the organic lesions were markedly affected, while the neuroses showed no disturbance.

A Case of Total Eventration.—Report of a case by C. G. Schmidt. The child was born by the aid of forceps. The viscera were covered only by peritoneum as a protection, through which they could be plainly seen. The child was seized with peritonitis and died on the fourth day.

Laryngeal Stenosis due to Complication of the Thyroid Cartilages.—Emil Mayer reports at length the case of a soldier who was struck on the right frontal bone by a Mauser bullet, which went through the superior maxilla downward and backward, cut through the posterior portion of the soft palate, and entered the neck. Here it was deflected, probably by the hyoid bone, and entered the thyroid cartilage, thoroughly comminuting it, cutting into the œsophageal wall, when, being spent, it dropped into the stomach. The eye had not been injured. Under cocaine anæsthesia, attempts were made to pass the hard-rubber fenestrated Schrötter tube of small calibre. These were used till dilatation occurred, followed by an attack of coughing by which a mass of lymph was ejected. A large chink resulted, and some air could be inspired, and the man was able to speak in a hoarse but strong voice. Larger-sized tubes were used, and finally a large-sized O'Dwyer tube was inserted. He was fed by means of the stomach tube. After a considerable course of treatment, the writer had a tube made whose head was as low as possible, with no retaining swell, and with a threaded opening for a screw piece, and finally a hollow introducer. Intubation was then simple. The patient was then sent away for change of air. His condition is materially improved, and he will, with an intubation tube that permits deglutition, probably attain eventually a perfect cure.

Gastro-Intestinal Hæmorrhage in the New-Born.—Edward H. Small reports a case of this nature. A long list of etiological factors has been given for this condition. Many more cases occur in institutions than in private practice—pointing to an infectious nature. Various organisms have been found. The course of the disease is very definite, soon ending in death or complete recovery; it is self-limited; the temperature is elevated; in most cases it is a general and not a local disease, not limited to one spot. These facts, together with its greater prevalence in institutions and the bacteriological findings, all point to its infectious nature and suggest its relationship to the acute infectious diseases. It is a very serious disease; the mortality, according to a number of authorities, varies from thirty-five to seventy-nine per cent. Various lines of treatment have been recommended, the most recent being the use of a solution of gelatin, both by mouth and by the rectum, with a favorable result in one case. The writer found his hypodermic use of morphine more beneficial than anything else.

Chronic Inflammation of the Tear Passages.—Willis O. Nance states that lacrymal disease constitutes from two to three per cent. of all eye cases. Females are more liable to the affection than males. The disease occurs at all ages. Chronic inflammation of the lacrymal sac sometimes occurs as a sequel of smallpox, measles, and scarlet fever. Syphilis, by necrotic inroads of the bony canal, may cause an attack of dacryocystitis by mechanical obstruction of the passages. The treatment should be directed (1) toward the removal of pathological processes and malformations of the nasal chamber; (2) toward the restoration of the patency of the pas ages; (3) toward the alleviation of all the factors conducive to the production of ocular irritation; (4) toward the proper correction of any existent dyscrasia.

Papillomata of the Larynx in Children.—Edward T. Dickerman concludes that: (1) Papilloma of the larynx is, especially in this country, a rare disease. (2) In a number of cases they undergo spontaneous cure. (3) Intralaryngeal methods should always be tried first, unless dyspnœa is pronounced, when tracheotomy should be done at once. (4) After tracheotomy, intralaryngeal methods should be tried. (5) The patient should wear a tube for six months after the growth has disappeared. (6) Thyrotomy should be considered only as a last resort.

Philadelphia Medical Journal, October 27, 1900.

The Etiology of Yellow Fever: A Preliminary Note.—Walter Reed, James Carroll, A. Agramonte, and Jesse W. Lazear, from their study of yellow fever, conclude that: (1) The blood taken during life from the general venous circulation, on various days of the disease, in eighteen cases of yellow fever, successively studied, has given negative results as regards the presence of bacillus icteroides. (2) Cultures taken from the blood and organs of eleven yellow-fever cadavers have also proved negative as regards the presence of this bacillus. (3) Bacillus icteroides (Sanarelli) stands in no causative relation to yellow fever, but when present should be considered as a secondary invader in this disease. From the second part of their study they conclude that (4) The mosquito serves as the intermediate host for the parasite of yellow fever, and it is highly probable that the disease is only propagated through the bite of this insect.

The Lancet, October 20, 1900.

The Treatment of Severe Cases of Diphtheria with Saline Infusions.—E. E. Laslett states that in the acute stage saline infusions are employed to dilute the toxin by the introduction into the system of an additional amount of fluid which helps also to flush out the kidneys. In the late stage they are used when along with the persistent vomiting, nutrient enemata are also rejected. Inasmuch as the fluids of the body are thus constantly diminished, the blood must become more viscid and the action of the heart be impeded. Saline infusions tend to prevent this state of affairs. Laslett used two teaspoonfuls of common salt to the pint of water, utilizing as a site of injection the loose skin below and outside of the right breast. Gravity was the force employed, the bag being held about three feet up. He found that from ten to fifteen ounces can be injected in half an hour. The child does not seem to mind the operation at all. Fifteen cases are reported. The only safe conclusion drawn (seven died, but the type was severe) is that the treatment seemed to have some influence in diminishing both the frequency of onset of symptoms of heart failure and their severity when they did occur.

The Prophylaxis of Malaria and the Destruction of Mosquitos in the Island of Asinara.—By C. Fermi and Dr. Tonsini. This island lies off the Italian coast and is used as a colony for convicts. The authors instituted measures for the destruction of the mosquito in the larval stage by pouring petroleum over all the stagnant water pools, by destroying the adult insects in the convicts' rooms by va-

rious powders, gases, etc., and by protecting the inhabitants against the insect, thoroughly screening and disinfecting them. The following is a summary of the results obtained: (1) The anopheles was almost never found in any of the dormitories, and the culex pipiens was much diminished in comparison with former years. (2) No case of primary malaria originating in the island was observed, for of the nine cases which occurred, two came from Castiadas, one from Isili, and six were relapses. In the preceding year there had been ninety-nine cases, of which forty had been contracted in the island.

The Clinical Study of Heart Disease.—Norman Moore, in a Hunterian lecture, discusses the significance of murmurs in general, and the differential features of those commonly met in clinical practice. He finds that one of the most difficult points to determine in relation to the physical examination of the heart is whether or no there is an adherent pericardium. In his opinion this diagnosis can be made with absolute certainty in only one case, and that is when mitral stenosis without other valvular lesion is present. This form of valvular disease is never on its own account associated with hypertrophy of the left ventricle. If, therefore, with mitral stenosis the left ventricle is hypertrophied and if there are no signs of chronic interstitial nephritis, then the hypertrophy is certain to be due to an adherent pericardium. This is a rare association of changes, and in every other condition the diagnosis of adherent pericardium is beset with difficulties.

The Value of Anti-Streptococcic Serum.—G. S. Walton reports two cases, both resulting in recovery; one was of a puerperal woman and the other of a child with a gangrenous throat in which diphtheria bacilli were present.

British Medical Journal, October 20, 1900.

A Clinical Lecture on the Prevention of Valvular Disease of the Heart in Cases of Acute Rheumatism.—Richard Caton outlines his treatment of acute rheumatism as follows: In the first place the rheumatism is stopped as soon as possible and all aggravation of it by chills prevented. The patient is kept absolutely at rest in bed, clothed from head to foot in a warm flannel garment. Salicylates are given in full dose, often with alkalies, and cholagogues in such measure as to cause free evacuations but no diarrhœa. The diet is confined to milk and light farinaceous food; no red meat is given for a long time. The patient is kept in bed long after all pain and fever are gone, for while the salicylate treatment removes pain and fever in twenty-four or forty-eight hours, it does not remove the rheumatic entity itself in less than two or three weeks of steady administration. Out of many hundreds of cases the writer has had only about fifteen per cent. of cardiac troubles, which is a low average. Even with this treatment there will be some cases of cardiac trouble, and of course it often happens that mischief in the heart has begun before the patient has presented himself for treatment. In such cases the patient must be kept strictly in bed, the head should not be raised, and no excitement be allowed. He must have the most perfect physiological repose possible. This will make the longest intervals between the systoles, and keep down blood pressure as far as practicable. Local help should be given to nature. This is accomplished by applying small blisters, each in size rather larger than a shilling, over the upper part of the chest between the clavicle and the nipple on either side. Only one blister is applied at a time, and after each a small poultice is placed on the blistered surface. This involves practically no pain. The principle of this treatment is the action of the blisters on the cutaneous nerves and the resulting stimulation of the trophic nerves of the affected part. This stimulation of trophic and vasomotor nerves results in extra nutritive and reparative activity, and restoration takes place which without such aid might not have been accomplished. The heart is in special relation with the first four dorsal intercostal nerves—this explaining the position indicated for application of the blisters. It is important that all inflammatory exudation should be absorbed and removed from the endocardium and valve cusps as early as possible. The iodides and mercury are used for this purpose. Rheumatism should be most carefully treated in children.

On Oöphorectomy in Cancer of the Breast.—In reviewing the history of this surgical procedure, Stanley Boyd refers to Beatson's suggestion in 1896, that the removal of both ovaries might be useful in the treatment of inoperable cancer of the breast, reasoning in the following way: In lactation there is rapid multiplication of mammary epithelium, the cells undergoing fatty degeneration as fast as they are formed; they then break down, fall into the lumina of the gland acini, and come away in the milk. In cancer the mammary epithelium also multiplies rapidly, but instead of undergoing fatty degeneration and being cast off, it distends the acini, penetrates into the lymph spaces of the breast, and there floating in a nutrient fluid it continues multiplying and forcing its way onward toward the lymphatic glands. Oöphorectomy in the cow maintains fatty degeneration of the epithelium of the lactating breast, and Beatson thought it might induce fatty degeneration of the epithelium of the cancerous breast. Accepting menstruation as the evidence of ovarian activity, he was inclined to believe that the cessation of lactation was due to the re-establishment of the influence of the ovaries, which influence had been suspended by the gravid uterus, and thus removal of the ovaries resulted in the indefinite continuance of lactation. He thought it possible also that cancer of the mamma might actually be due to some "ovarian irritation" or to "some defective steps in the cycle of ovarian changes," and that their removal might bring cancerous cell-proliferation to a standstill or induce fatty degeneration of the cells as in lactation. The writer presents a table of forty-one cases. He also knows the results in thirteen other cases, making a total of fifty-four. Of these fifty-four cases, nineteen (thirty-five per cent.) were more or less markedly benefited, thirty-four were not benefited, or only doubtfully so, and one resulted in death from exhaustion. He believes that oöphorectomy should be offered in cases other than the very acute, in women over forty, with no visceral or bony lesions, in fair condition, and before the menopause. In extensive primary cases and recurrences as much as possible of the disease should be removed; healing should be attained, lest the operation fail in its object and malignant ulceration be started. Work must still be experimental. The writer believes it desirable to amputate arms which are so heavy from œdema that by their weight they prevent the patient from getting about—this, of course, at the patient's request.

A Well-Marked Family Predisposition to Various Manifestations of the Rheumatic State.—H. T. Nixon reports the following family history: The father and mother had not suffered from acute rheumatism; the paternal grandmother had had seven attacks of this disease and finally died from heart disease. As to the children: (1) Male, aged twenty-five years; suffered from first attack at age of fifteen, and six weeks after convalescence had a second attack; now has mitral stenosis and regurgitation. (2) Female, aged twenty-two years, has not had rheumatism. (3) Male, died at fifteen from acute rheumatism and heart disease; was an epileptic. (4) Female, aged seventeen years; first attack at fifteen during which she developed mitral regurgitation; she was in bed a month and developed chorea at once on leaving bed. At seventeen a second attack was ushered in by tonsillitis. During this attack she developed pericarditis, pleurisy, aortic stenosis, and regurgitation, and later subcutaneous nodules appeared over both external malleoli. (5) Female, aged fifteen years; had chorea every spring for three years; the fourth year an attack of rheumatism during which mitral regurgitation developed. (6) Female, aged twelve years, no rheumatism, but chorea at eleven, and now has mitral stenosis. (7) Female, aged ten years; had acute rheumatism and now has mitral stenosis and regurgitation. (8) Female, aged eight years, has not had acute rheumatism. Four of this family were attacked by this disease one after the other and were in bed at the same time. The writer has obtained a rheumatic family history in sixty-two per cent. of his one hundred and three cases.

On the Resting Position of Anopheles.—L. W. Sambon and G. C. Low criticise the report of Mr. Austen in regard to the position taken by mosquitos when resting. The writers in their observations have noted that the Anopheles belonging to the species claviger (Fabr.) never stand on their heads but rest on their feet with the posterior part of the body slightly inclined away from the support on which they rest. The inclination of the body was less when the insect rested on its three pairs of legs, and formed a maximum angle of about 45 when it poised on the two first pairs and stretched out the last pair free. Both Culex and Anopheles frequently sit with the last pair of legs lifted away from the support. But while the legs of Anopheles claviger stretch out with the tarsi pointing downward, those of the various species of Culex observed by the writers presented the tarsi curled upward in a very characteristic manner. He adds that it is evident that the observations made by Ross and Austen in Sierra Leone were quite

correct, but that they erred in extending to the whole genus a character which is peculiar to a few species which they had observed only in Anopheles costalis. Although the resting attitude of mosquitos is not important in the diagnosis between the Culex and Anopheles genera, it will always be valuable in the differentiation of species.

Four Cases of Recurrent Mammary Carcinoma Treated by Oöphorectomy and Thyroid Extract.—G. Ernest Herman refers to the reports of two cases, and gives the history of the last two cases of this nature. Benefit was experienced in each instance. After referring to Boyd's table, in which seventeen cases seemed to have been favorably influenced by the operation, he adds that twelve of these patients had been given thyroid extract. Twenty-one cases were not benefited and only five of these had had thyroid. This would point to the extract as being concerned in the result. He believes that the fact that benefit does follow the combination of oöphorectomy and thyroid extract should first be established and later the cases be defined in which benefit might be expected. Then it can be decided what share of the result each factor in the treatment is entitled to.

Cyclic Albuminuria of Adolescence.—The author of this paper, H. Dauchez, in his report of two cases, shows that this affection can sometimes be associated particularly with the gouty diathesis and sometimes with an infection, *e.g.*, typhoid fever. Dauchez has studied especially the first of these forms, and gives the following notes: The patient, a girl aged thirteen years, suffered continuously from evening albuminuria in December, 1898, and during the first five months of 1899 excepting April—in the beginning influenced by milk diet. The patient, of undoubted gouty ancestry, arthritic and diabetic, was very rapidly relieved by the milk diet. The evening albuminuria reappeared periodically during six or eight months at the menstrual epochs, independent of atmospheric influences. Intercurrent febrile affections caused a distinct but transitory albuminuria. This trouble seems associated with a profusion of leucocytes in the urine, as well as epithelial débris and oxalate crystals, but no casts. The kidneys always remained permeable to methylene blue. The patient was cured at the end of the tenth month, but she had had every month a discharge of albumin in the evening with no appreciable cause, varying from 0.50 to 3 gm. She has now passed four months without albuminuria. Arthritis, gout, menstruation, and adolescence predispose to this renal trouble without fever. The fevers cause a return of the condition. Pregnancy can also have the same effect. Without a course of treatment very severe and very prolonged, which is absolutely necessary for cure, marriage ought not to be advised.—*Journal des Sciences Médicales de Lille*, October 6, 1900.

Experimental Repair of Tissues.—Paul Carnot speaks of the different processes of repair of tissues, whether they take place in the course of normal life, or follow the local action of a traumatic substance, or are the result of a diffuse infectious toxin. In the first case the method of repair is so diffuse that it is difficult to observe. The repair following traumatism is most favorable for experimental analysis. The repair following the lesions caused by infectious toxins is like that in the first class, generally diffuse and hard to study. Most tissues are capable of a certain plasmogenic power and can proliferate actively. There are certain biological conditions which greatly influence tissue repair: local infections, for example, hinder regeneration of tissues and cause fibrous cicatrization, or even the complete absence of repair. On the other hand, several mechanical or chemical excitants of cellular proliferation are known: mechanical contact of an inert foreign body, massage of tissues, iodine, cantharides, certain saline solutions, and certain toxins in small doses. Organic extracts have an action on the homologous organ. If we are still in almost absolute ignorance of how to influence morphogenic function, we may influence the plasmogenic function of tissues in partly regulating and directing cellular proliferation, and so causing repair of tissue.—*La Presse Médicale*, October 3, 1900.

Concerning the Gravity of Rheumatism in the Child, from the Point of View of Cardiac Complications.—M. H. Barbier declares that articular rheumatism in children is an affection of grave import on account of the frequency and severity of the cardiac lesions incident thereto. Various authorities state the percentage of cardiac affections to be eighty-one per cent., or even as high as eighty-seven per cent. The onset of rheumatism is often marked by general phenomena, fever, headache, vomiting, etc., which show that in children rheumatism has more the course of a general infectious malady than that of a multiple arthropathy, and that the visceral localizations in the heart in particular are not in relation to the intensity of the articular manifestations. The majority of cases of rheumatism in children which Barbier has observed, accompanied by more or less grave cardiac complications, have yielded in a few days to treatment by sodium salicylate. Death may occur in from three to six months after the beginning of rheumatism in children previously in good health. It is probable that the severity of the cardiopathies in the child are mainly due to pericarditis. It causes in a great number of cases a fatal termination.—*Journal de Médecine de Paris*, October 7, 1900.

Alimentary Glycosuria in the Gastro-Enteritis of the New-Born.—Eugène Terrien reports the results of forty-two examinations of alimentary glycosuria in nurslings suffering from gastro-enteritis. In order to obtain reliable results, it is necessary to conform to a uniform technique (nature of the sugar employed, dilution, mode of administration). Alimentary glycosuria occurs physiologically in the infant only when the dose is raised to 5 gm. of sugar or less of pure glucose, 4.5 gm. of pure lactose to a kilogram of body weight. In gastro-enteritis it occurs with doses of 3.5 gm. and even less. Alimentary glycosuria was observed in nearly half the cases. It is in direct relation with two factors: diarrhœa and emaciation. Perhaps a conclusion as to the functional insufficiency of the liver might be drawn from these results, but the author does not wish to encroach on this subject.—*Journal des Praticiens*, October 6, 1900.

Lipomata of the Parotid.—Baudet speaks of the rarity of these tumors, and classifies them under three heads: (1) Superficial subaponeurotic lipomata; (2) deep subaponeurotic lipomata; (3) intraglandular lipomata. The size is variable—half a hen's egg, a lemon, etc. An adeno-lipoma the size of an infant's head has been recorded. These tumors occur as a rule between the ages of thirty and fifty years. The parotid lipomata hitherto recorded have been on the left side. Their growth is slow and regular. The diagnosis is difficult. Cysts and enchondromata must be excluded. Ablation by a bistoury is the only treatment, when they are large enough to be removed.—*Gazette des Hôpitaux*, October 6, 1900.

Treatment of Dysentery by Methylene Blue.—M. Berthier calls attention to the histological origin of this substance as a medicine. It has been widely used in the laboratory. As used in dysentery it is interesting from several points of view: Its simplicity is recommended in comparison with mercury, which is managed with difficulty, and as compared with ipecac, which is not well borne by the organism. Methylene blue is efficacious and rapid in its action. It quickly causes the pain of this illness to subside. It is a parasiticide, cholagogue, and its effects are soothing, while it exerts no harmful or irritating action.—*La Médecine Moderne*, October 10, 1900.

Boiling Water in Local Infections.—Moty concludes that: The action of boiling water is much superior to that of hot water; it is more easy to localize and more penetrating than gas at a high temperature, and does not require any special preparation. It ought, on account of its power, to be used carefully. Its action is rather tonic than antiseptic. So far it does not appear that the cranial and thoracic cavities can be subjected without danger to the action of

hot water, which ought elsewhere to be carefully accommodated to the important organs which may be in the neighborhood of the part to be treated.—*Le Bulletin Médical*, October 6, 1900.

Contribution to the Treatment of Psychoses by Repose in Bed.—Casteras concludes that repose in bed has a quieting effect on the organism; it attenuates the symptoms, but has only a little influence on the course and duration of psychoses; it facilitates the supervision of patients, but is accomplished at much expense; this method cannot be a general one, but is only an addition to other therapeutic means; it ought to be based on perfect knowledge of the personal idiosyncrasies; its employment has not always given the results hoped for.—*Le Nord Médical*, October 1, 1900.

Menstrual Troubles in Certain Maladies of the Stomach.—M. Boimond states that these troubles are observed chiefly in neuro-arthritic patients. They are dysmenorrhœa and amenorrhœa. The most frequent cause is dilatation of the stomach with hypoacidity; hyperacidity is rarer. Menstrual troubles without anatomical lesion are a nervous syndrome observed in predisposed subjects.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, October 4, 1900.

Münchener medicinische Wochenschrift, October 9, 1900.

A Case of Hysterical Fever.—Wormser and Bing say that the prejudices which existed formerly against a belief in the possibility of fever of purely hysterical origin are now without foundation, since the existence of one or more heat-regulating centres has been proven. Just as any of the motor or sensory centres may be involved in a hysterical seizure, so the heat centre is not exempt and may exhibit disturbances of function due solely to nervous impulses. Although such cases, when reported, have always been regarded with a good deal of professional scepticism and considered as explicable either on the ground of unrecognized organic lesion or malingering and deceit on the part of the patient, there are some instances on record in which such fallacies could be excluded, and this number the authors increase by a very detailed account of a case coming under their own observation. The patient, an unmarried woman aged twenty-four years, with a very neuropathic family history, at the age of puberty manifested the first signs of a rapidly developing hysteria of medium intensity. In addition to various subjective and objective stigmata elicited in the history there were actually present under observation anæsthesia, analgesia, hyperæsthesia, dermatographia, migraine, ovarian crises, diplopia, contracted visual field, achromatopsia, astasia-abasia, tremor, and convulsive seizures. The hysterical temperament was well marked in the emotional crises, the instability of temper, precocious and excessive sexual irritability, and the tendency to exaggeration and simulation of symptoms. Under these conditions, in consequence of gonorrhœal infection pelvic trouble developed which necessitated first the partial and then the total ablation of the uterus and adnexa. The abdominal condition was greatly improved by the operation, but the inauguration of the artificial menopause was followed by unusually stormy molimina; in addition to the customary vasomotor disturbances—headache, obesity, etc.—a greatly increased tendency to hysterical attacks manifested itself, which was especially well marked at the time of the periods. After several such seizures, eight weeks after operation the patient suddenly ran up a temperature of 104.7° F., which dropped back to normal again in a space of three and a half hours. This disturbance of the heat-regulating function was followed by an attack of hysterical *petit mal* with delirium and unconsciousness. The fever was not due to the muscular energy liberated during the convulsion, since this did not occur till after the drop had commenced; and the minuteness with which other possible causes were searched for and eliminated apparently leaves no doubt that this is an indubitable case of high fever due solely to nervous disturbances.

The Occurrence of the Bacillus Xerosis in Progressive Phlegmon, Secondary Wound Infection, and Otitis Interna.—Warnecke in three different cases was able to isolate an organism corresponding to the bacillus xerosis in its biological characteristics. In the first of these, operation for a chronic fetid suppuration with ostitis of the mastoid was followed by extensive infiltration of the tissues and progressive cellulitis which invaded the neighboring areas of the scalp and in the neck reached down to the clavicle. There was great discoloration of the parts invaded, with burrowing in all directions, and even the most energetic treatment was unavailing to check the spread of the process. At the autopsy there were found purulent arachnitis with thrombosis of the sigmoid, transverse, and occipital sinuses, with metastatic abscesses in the lower lobes of both lungs. The second case is also one of secondary wound infection, but ended in recovery, and resembles the first only in the presence of the same organism, the high temperature, and the intense discoloration of the wound edges. In the third case a fatal arachnitis with metastases in the lungs was produced by the same bacillus. The organism resembles the diphtheria bacillus in appearance, and segmented and involution forms are frequently present. Different cultures showed great polymorphism, and agar culture apparently furnishes the most favorable medium; bouillon growths evincing a tendency to the club shape even when only twenty-four hours old. Gelatin is not liquefied, bouillon is made cloudy and shows a deposit in twenty-four hours, and glucose is not fermented by the bacillus, which imparts an acid reaction to litmus whey.

A Case of Acute Formalin Poisoning.—J. Klüber describes a case which is interesting in being probably the first reported instance of formalin poisoning. The patient, who had accidentally swallowed an unknown amount of a weak formalin solution, was found unconscious and covered with cold perspiration, but at first did not exhibit any other symptoms. The stupor, which resembled that accompanying alcoholic intoxication, persisted for a number of hours; there was complete anuria for nineteen hours and redness of the conjunctiva and pharyngeal mucosa. The diagnosis was made by the chemical examination of the fluid drunk and the demonstration of formic acid in the urine. The treatment was apparently symptomatic, and the patient made a good recovery.

Metapneumonic Abscess, with Pure Cultures of the Diplococcus Pneumoniæ.—By Roeger.

Berliner klinische Wochenschrift, October 1, 1900.

Physiology and Pathology of Bile Secretion.—Albu reports certain observations made in the case of a woman with a biliary fistula. The latter had existed for nine years. Various diets were taken, and it was found that one of milk, eggs, soup, white bread, vegetables, and fruit caused a more abundant outflow of bile than a diet in which meat figured largely. The author thinks that it is not possible to determine from experiments on animals just what remedies will in man produce an increased bile flow, and thinks that many investigators have mistaken an outflow of bile from accumulations in the various biliary reservoirs for an actual increase in its formation in the liver cell.

Experimental Bence-Jones Albumosuria.—G. Zuelzer's observations were made on the case of a dog which had been poisoned with pyrodin. In the course of the case albumose appeared in the urine, and Zuelzer believes that this is a constant feature of this form of poisoning in dogs. Other observers have found it for a short time, but it has been covered up by the albuminuria which quickly appears. In the animal of Zuelzer, the albumosuria lasted for five days before albuminuria appeared. The former substance has been found in cases of myelogenous sarcoma in the human organism and regarded as pathognomonic therefor. Doubtless some of the instances in which the so-called peptonuria has been found in pernicious anæmia were really cases of albumosuria.

Internal Hydrocephalus following Cerebro-Spinal Meningitis.—Elliott P. Joslin reports a case, with accounts of seven other cases. Internal hydrocephalus has been known to be a result of epidemic cerebrospinal meningitis since 1805. The symptoms consist of paroxysms of severe headache, and also of pains in the neck and extremities, with vomiting, unconsciousness, convulsions, and involuntary evacuations of fæces and urine. The attacks either occur in a fairly regular type, or make pauses which not rarely last for weeks, during which the activity of the mind and senses may be unimpaired, the appetite excellent, the sleep restful, and the patient in good spirits and gaining strength. If we fall into the error of supposing that the disease has taken a favorable turn, a new attack dispels the illusion. Generally speaking, the cure of secondary hydrocephalus is impossible, but Ziemssen states that he has seen some cases in which a complete, and others in which an incomplete, recovery took place.

Primary Splenomegaly; Endothelial Hyperplasia of the Spleen.—David Bovaird reports two cases in children, with autopsy and morphological examination in one. He thus summarizes their clinical relations: Case I.—Great en-

largement of both liver and spleen, simple anæmia, slight enlargement of superficial lymph nodes. Case II.—Enormous splenic enlargement and moderate enlargement of the liver, simple anæmia, slight enlargement of superficial lymph nodes; affection of thirteen years' duration. Patient's sister had enlargement of spleen beginning at practically the same age. It may therefore be safely assumed that whatever the disease, it is the same in the two cases. From both the history of the patients and the clinical observations, it is apparent that the enlargement of the liver is secondary to that of the spleen. The author holds that these cases represent an affection hitherto unrecognized.

The Value of Pedicled Flaps in Injuries of the Hand.—W. E. Schroeder says that when one desires simply to cover the palm, dorsum of hand, or the palmar surface of the thumb, flaps may be taken with freedom from the chest or abdomen. When the palmar surface of the fingers has been destroyed, it is much better to have double pedicles, and these can best be obtained from the hip. Furthermore, this position is reasonably comfortable. In young and old patients, however, such a procedure would be very trying and scarcely justifiable. The advantages of the method are: (1) Mobility; (2) elasticity; (3) certainty of taking.

Sarcoma and Cirrhosis of the Liver.—W. W. Ford reports a case in which the presence of cirrhosis of the liver was explained by the intemperate habits of the patient. It is more difficult to explain the presence of a huge mass of sarcomatous tissue in the right lobe of the liver. It was a definite sarcoma of a combination of round and spindle cells, and its presence cannot be explained unless it be considered as a primary tumor. Its association with cirrhosis of the liver must be considered quite unique.

Distortion of the Aorta in Pott's Disease.—By Thomas Dwight.

Journal of Laryngology, October, 1900.

Treatment of Otitic Pyæmia.—Dundas Grant says that expectant treatment is useless. Non-surgical treatment consists in the use of diuretics and purgatives, and in the pure septicæmic cases of alcohol, quinine, ammonia, and nourishing diet. Antistreptococcus serum may be injected. Surgical treatment should commence with free incision of the drum membrane, removal of broken-down desquamated epithelium in the tympanic cavities, and in the presence of pyæmic symptoms the petromastoid cavity must be opened without delay. In acute cases, the mastoid cells and antrum must be freely exposed, all diseased bone and granulation tissue scraped away, and the peripheral cells be opened up to the very tip of the mastoid. In chronic cases, if there is evidence of thrombo-phlebitis of the jugular vein in the neck, this may be ligatured previous to the radical operation. In the absence of such evidence we proceed at once with the radical operation, and then expose the sigmoid sinus by a continuation backward of the breach in the bone and explore it. If it is thrombosed and there is evidence of puriform disintegration high up in the sinus, it may be freely incised and the purulent débris removed with a spoon. If firm healthy clot occlusive is reached the cavity may be cleansed with sublimate solution, dusted with iodoform and boric acid, and lightly plugged with iodoform gauze.

Pathology and Treatment of Toxic Paralyses of the Larynx.—Watson Williams sums up the treatment as follows: (1) We should resort to appropriate general treatment of the infective disease when that is the cause of the paralysis. Measures should be directed to the removal of the poison in the circulation and tissues in the case of organic or metallic poisons. (2) The faradic or galvanic currents should be applied to the interior of the larynx. Strychnine may be given by the mouth in considerable doses. When feasible, it should be injected directly into the muscles. (3) Intubation or tracheotomy may be necessary to relieve dyspnœa and threatened asphyxia in cases of bilateral abductor paralysis.

Naked-Eye Diagnosis in Cancer of the Larynx.—J. N. Mackenzie says that it is impossible to exaggerate the importance of naked-eye diagnosis in the detection of laryngeal cancer. Taking it all in all, it is by far more practical than either thyrotomy or the microscope. Unfortunately in most quarters it is relegated to a subsidiary place. Even the best of laryngeal surgeons lose no time in procuring portions of a suspected growth for microscopic examination before they have gone thoroughly into the history of the case and carefully endeavored to make the diagnosis with the naked eye alone.

Archives of Otology, August, 1900.

Diseases of the Organ of Hearing in Pernicious Anæmia.—Schwabach reports seven cases, in five of which subjective noises were present; by three of these patients the noises were heard in both ears and by two in one ear only. The two remaining patients could give no information on this point on account of their condition (delirium, somnolence). Deafness was complained of by three of the five patients by whom subjective noises were heard, but in one of them only one ear was affected, and in another the deafness of one ear was due to an old traumatism, so that this ear must be left out of account. There remain, therefore, four ears in three of which the hearing was markedly impaired (voice close to ear), while the fourth could distinguish whispered words at 2–3 *m*. Accurate tests with tuning-forks could be made in only two of the patients, comprising three affected organs of hearing, and in another air and bone conduction were tested with fork c only. The results of the examination of the first three ears were as follows: Low forks (16, 32, 48 vibr.) were not perceived in any case; c (128 vibr.) and c^{iv} (2048 vibr.) also were not heard by one of the ears, while the period of perception of the two remaining ears was shortened for these forks. In two of the ears perception of c through mastoid was lengthened by 7 and 2 sec. respectively, in the other shortened by 4 sec. Rinné was negative in two ears, and in the third was of no value as a test since c could not be heard at all through air.

Upon the Color of Living Rhachitic Bone as Found during Mastoid Operations in Rhachitic Children.—Muck says that in major operations the aurist has presumably greater opportunity than the general surgeon to see the interior of a rhachitic bone, for he frequently meets with cases of purulent inflammation of the pneumatic cavities of a mastoid process and of purulent disintegration of the surrounding bone in rhachitic patients. The macroscopic condition of a rhachitic mastoid during life differs from that on the post-mortem table, where the bone, by decreased blood supply, and perhaps also by other post-mortem changes, has lost the bright rose color which it has during life. Only its softness, offering no resistance to the knife, is alike both in living and dead bones. The light rose color is not due to the hyperæmia of underlying structure shining through the chalkless bone, for it is the same at the thin squamous portion of the temporal bone as it is at the compact (not yet pneumatized) parts. It is solely brought about by the increase of the vascular and medullary formations. It is remarkable that this hyperæmic bone does not bleed upon chiselling, as we are accustomed to see it in infectious inflammations of the bone. An illustrative case is recorded.

Two Cases of Otitic Lateral-Sinus Disease; Operations, with Ligation of the Jugular.—Concerning the latter operation O. Joachim says that other avenues of infection on one hand, and the presumption of an occluding clot in the jugular on the other, seem to argue against the necessity of always tying the jugular, aside from the statistical position of the question. The preponderance of recoveries being in favor of the cases in which ligation was made, he personally favors it when a high degree of pyæmia is evident, securing the patient against an important avenue of infection. When ligation is performed it appears to him that the vein should be resected at once as high up as possible.

Dublin Journal of Medical Science, October, 1900.

The Prevention and Treatment of Post-Partum Hemorrhage.—J. W. Byers describes the various causes leading to this accident, and says that the two measures which should be adopted in every case to prevent post-partum hemorrhage are: (1) The proper management of the third stage of labor; (2) the important principle, never to deliver in the absence of pains. Treatment consists of the following measures, mentioned according to the author's ideas of their relative importance: External uterine massage and hot water through a double-current tube, hand in the uterus, bimanual compression, gauze plugging of the uterus, drawing the organ downward by means of a vulsellum forceps passed through the lips of the cervix ("kinking" and compressing the uterine arteries), and injection of iron. The latter is a remedy not without danger; it causes a certain amount of superficial injury of the uterine wall, which forms a suitable nidus for the growth of germs, and if it fails, plugging cannot be done, owing to the effect the iron has on the tissues.

The Delusive Stage of Grave Abdominal Lesions.—J. S. M'Ardle calls attention to the subsidence of symptoms in grave abdominal conditions which is often hailed as an evidence that the patient is on the road to recovery, but which is often followed after twenty-four to forty-eight

hours by intermittent attacks of mental aberration, erratic temperature, abdominal distention, delirium, rapid pulse, and death. He details a series of appendectomies, describing his personal method of operating. The paper is a plea for timely operation in the class of cases suggested by the title.

Remarks on Senile Dementia.—C. Norman recites several clinical histories illustrative of the various phases of senile dementia. He finds the condition more common among women of the lower classes who are addicted to alcohol. Special symptoms discussed are restlessness, hypochondriacal delusion—suspicion, amnesia, aphasia and paraphasia, disorientation, and sexual excitement.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PLAGUE, ITS PREVENTION, ETC.—MEDICAL SOCIETIES—THE ROMANCE OF SURGERY—SIR JOHN WILLIAMS ON CLASSICAL EDUCATION—THE PUBLIC HEALTH.

London, October 12, 1900.

No fresh cases of plague have occurred at Glasgow. One man died on the 7th inst. He was admitted on the 20th ult. A fatal case occurred at Cardiff on the 4th. The case in Wales proved to be that of a man from the same ship as that at Cardiff. Another man from that ship was landed at Kings Lynn with typhoid fever. He has been carefully watched and is now convalescent. These events illustrate the need of our local authorities being on the alert, and hitherto they have been so.

The local government board has issued a "plague memorandum." This asserts that the disease "will not readily fasten upon that section of our population which is properly housed, cleanly, and generally in a sanitary sense well to do; that rather it will especially affect, if it obtains foothold in one or another district, insanitary areas such as are peopled by the poorest class, and where overcrowding of persons in houses and dirt and squalor of dwellings and of inhabitants tend to prevail." The memorandum also gives a brief account of the symptoms of plague and points out the importance of recognizing those cases in which buboes are not found. The board has also circulated directions for obtaining and forwarding material from suspected cases for bacteriological examination without cost. Moreover, the board is prepared to supply Haffkine's serum to the medical officer of health of any district that may be invaded.

The London County Council is also prepared to meet an emergency and has informed the government board of the precautions it has taken and the preparations it has made for isolating "contacts" should an invasion occur. Among these measures is the retaining of Mr. James Cantlie to examine and report upon suspected cases and to make post-mortems when necessary. Mr. Cantlie had large experience in one of the plague hospitals at Hong Kong where he resided for many years. An arrangement has also been made with Dr. Klein for bacteriological examinations.

Inquiry has been made in all lodging-houses and shelters in districts likely to be visited, with the encouraging result that not a single case of illness suggestive of the infection has been discovered up to this date.

Professor Zabolotny, of the Russian commission on plague, has visited Glasgow, and as I have not given you any account of the peculiarities of the cases there you may like to have his conclusions. He says (1) the Glasgow epidemic compared with that of India, China, and Africa, as well as recent outbreaks in Europe, is of the mildest description. (2) The extension of the epidemic is slight and the mortality insignificant, which may be attributed to the excellent sanitary and medical arrangements in Glasgow. (3) Bubonic cases are less dangerous from a point of view of epidemiology than the pneumonic forms. The latter are excessively contagious because the sputum teems with the bacilli. (4) Since in the bubonic form it spreads by contact with the skin, isolation and cleansing of linen and clothing play the chief rôle in prevention. (5) For those in contact with the sick the best preventive is injection with serum as practised at Glasgow. (6) So the best treatment is serum by intravenous injections of large doses. (7) The post-mortems of fatal cases at Glasgow have shown the appearances of protracted illness, not those of acute plague lasting two or three days.

The session of the societies has opened. On Monday evening Mr. J. H. Morgan assumed the chair at the one hundred and twenty-eighth session of the Medical Society of London and delivered the inaugural address. He took for his subject the "Romance of Surgery." His discourse may be described as a brief survey of the present condition of surgical art contrasted with that of a quarter of a century ago, and then an endeavor to anticipate its further progress in the more or less near future. Listerism naturally took the first place in his review, for it is not much more than twenty-five years since that had been accepted. Mr. Morgan's first case of treatment by the antiseptic method was in 1873, when he was house surgeon to Mr. Pick. It was a wound by a circular saw which had divided the patella and incised the outer condyle of the femur. Some suppuration occurred and the patient recovered with an ankylosed knee. At the time it was looked upon as a triumph, since such cases were then usually amputated and pyæmia often followed. This case was contrasted with one lately treated by the perfected antiseptic method which is now universally practised. A man had driven a chisel through his knee joint into the condyle and was well in a few weeks with complete and perfect movement of the joint. Abdominal surgery, malignant disease, wounds in war, prostatic disease, and the *x*-rays were among the illustrations given of the "Romance of Surgery." The fancy, too, that once deluded surgeons that in fractures they had reached finality has been dismissed, and it is said that our methods are altogether wrong. Startling as this is, we may pause to ask whether the disturbance of tissues involved in wiring and screwing may not do more harm than the older methods.

In conclusion he hoped the co-operation of physician and surgeon to ease the sufferer may continue to grow stronger, for in their union is strength and to relieve is the end and object of our art.

The introductory addresses still occupy a fair share of our conversation—not so much as to complete lectures as to little points that have dwelt in the memory of hearers and are passed on to others.

Sir John Williams, a good Welshman, went to Wales and discoursed on Greek and Latin at the University College of South Wales. He is evidently at one with the modern outcry against the classics and in favor of the sciences with modern languages as the best outfit for medical study. He remarked that a classical education is pursued mostly, not for the culture it gives, but in order to acquire instruments for special pursuits—such as theology, law, philology, history, teaching, etc. The instruments are necessary to them, but not for the pursuit of science. As to medicine Greek is no longer compulsory, and the knowledge of Latin demanded of the medical student is so small that it does not enable him to read the easiest Latin book except with difficulty and the help of a dictionary. Thus the long time often spent upon it is wasted. In addition to ordinary school subjects Sir John would give a thorough course of the English language and literature. This would give him a vocabulary, a command of language, a taste for good literature, and a larger, better culture than a smattering of Latin too scrappy to be of any real use. He would also have them learn French and German as necessary for leaders of the profession.

Then he diverged to tell his hearers some distinct advantages of a knowledge of the Welsh language and literature which he rejoiced would receive due recognition now that Wales had its university.

The number of cases of typhoid in the hospitals of the asylums board increased last week by forty, and fifteen fatal cases are reported. The deaths from scarlet fever rose from five to fourteen. Over two thousand cases of this disease are reported—an increase of one hundred and thirty. Still the general death rate of the metropolis is lower than it has been for about twelve weeks.

LETTER FROM CONSTANTINOPLE.

(From our Special Correspondent.)

THE PLAGUE—A PROPOSED NATIONAL UNIVERSITY FOR TURKEY—MEDICAL STUDY—THE MEDICAL ASPECTS OF THE SULTAN'S FÊTE—DEATH OF DR. SAVELL—NEW PHYSICIAN TO THE BRITISH EMBASSY—ACCIDENT TO DR. RIEDER.

Constantinople, October 1, 1900.

The presence of plague in the Levant has not excited the degree of anxiety that might have been expected, whether it be that there is more confidence in the sanitary administration, or that—from Constantinople having so often escaped epidemic influences—the population have shown much indifference.

A false alarm of plague in the city caused Bulgaria to impose a quarantine of eleven days, which, however, was removed within forty-eight hours. Since then the "Messagaries Maritimes" S. S. *Niger* arriving from Alexandretta and Beyrout undoubtedly brought plague. In connection with this outbreak of plague there was a "fiasco," as it was mildly put. The passengers were landed and scattered before the existence of the disease was discovered or declared. When it was known, much excitement

and alarm were created in sanitary and unsanitary circles. The passengers were placed under "surveillance." The vessel was quarantined to the station of Clazamine and exposed to the routine of disinfection. Other cases occurred on board, among them the doctor of the ship. Nothing, however, transpired of any case on shore. The mode of communication is not very evident. The *Niger* touched at Alexandretta and Beyrout. At the former place an Armenian boy, said to have escaped from the locality of the alleged massacres, near Sassam, was taken on board as passenger. The boy had travelled on foot through the country lying between Sassam and Alexandretta, a journey of from sixteen to twenty days. There is no evidence of the existence or prevalence of plague in that part of Asia Minor, so it is impossible to trace the source of infection, though it may have been communicated at Beyrout, where there had been reported isolated cases of plague. The Ottoman Sanitary Service is a very "cock-sure" institution, and much sarcasm has been indulged in with reference to the landing and scattering of the passengers of the S.S. *Niger* before the presence of plague was known or declared.

This time there could be no doubt of the city being compromised, and naturally, in accordance with practice, Russia, Greece, and Balkan States imposed quarantine, which is still continued in a modified form. Now, contrary to the practice of former years, there has been no disposition on the part of these countries to stretch to the utmost the limits of the system. The laxity of observation in relation to the cases on board the *Niger* is not easily explicable.

The great event of the year so far is the celebration of the twenty-fifth anniversary of the accession of His Imperial Majesty, Sultan Abd-ul-Hamid, to the throne, and certainly the form of commemoration is worthy of notice in its medical aspects. It has been already noticed that His Majesty has always shown a deep interest in all matters relating to the education of his people, and that during his reign more has been accomplished than by his predecessors. It would appear as if the crowning stone of this educational edifice had been placed by the creation of a university for Turkey. This intention had been declared beforehand, but the official inauguration has taken place, professors have been appointed, and even students nominated.

Medicine is as fully represented in this university scheme as other sciences are, and probably will be more kindly fostered by authority; inasmuch as the Turks—like Easterns of all classes—take kindly to the healing-art. Mystery, formerly so associated with the practice of physic and religion, has not yet lost hold on the Turkish mind.

On the other hand it must be borne in mind that this university cannot be considered a product of the evolution of very advanced education and science. The idea probably originated thus: all countries in Europe possess universities. The time has come for Turkey not to be behind; therefore, "let there be a university in Turkey," and it is so. No idea of evolution. But as there has been real educational progress in Turkey for some years past, and especially medical education, it will be interesting to watch the working of this institution.

The medical world was prominently represented on this occasion by the "Imperial Society of Medicine," the "Society of Pharmacy" and other allied bodies, one and all declaring how much His Imperial Majesty has contributed to the development of medicine, pharmacy, and their allied branches during the twenty-five years of his reign. Honors and decorations have been liberally bestowed, of which the medical profession has had a full share. An address to the throne summarizes thus: "Ameliorations which enable the faculty of medicine to compare favorably with foreign faculties; the native teachers are increased and replace the foreign recruits. The new faculty of medicine and its annexes of hospitals, clinics, laboratories of chemistry and bacteriology, museum of natural history and large botanical gardens, as in former days, all of which will worthily form part of the grand university just ordered to be made. Council of civil medical affairs to judge all medical affairs of the empire; salutary measures for the exercise of medicine and pharmacy; a superior council of hygiene; the sanitary administration of the empire against invasions of epidemic diseases by an international council of health"—which boldly proclaims its functions and claims to have barred the doors of the empire against invasions of epidemics (*vide* S.S. *Niger*). "The creation of numberless hospitals in the provinces; a maternity hospital at Hasskien; an hospital for children (the Hamidiah) at Chichli; an asylum for the poor; hospitals against the propagation of syphilis in the provinces; an antirabic institute; a vaccinal institute; the restoration of the baths at Yalova (of which more anon), and the institution of local dispensaries."

No wonder, then, that with such favorable opportunities of distinction there should be an inundation of doctors of every nationality, and of both sexes, seeking permission to practise; their ages varying from twenty-three to sixty.

Dr. Richard Savell, a surgeon of considerable repute, well known to his colleagues abroad, died suddenly on September 3d. Dr. Savell was the first surgeon in Constantinople to perform ovariotomy on the new basis of antiseptic and aseptic surgery. He was professor of clinical surgery in the medical school and a bold and successful operator.

Dr. Frank Clemow has succeeded the late Dr. Dickson as physician to the British embassy, and delegate to the Ottoman health council.

A sad accident has just occurred (October 4th). Professor Dr. Rieder, inspector of schools of medicine and chief of the hospital at Gulhané, visited, in company of the architect, the new school of medicine at Haidar Pacha, in course of construction. In consequence of a false step he fell a distance of over forty-five feet. His tibia, it is said, is fractured, and he has sustained other grave injuries of the head and spinal column. His condition is stated to be dangerous.

THE NATURE OF HYSTERIA.

To the Editor of the Medical Record.

Sir: I read in the Medical Record of August 25, 1900, a paper by Alfred Gordon, M.D., in which the following passage occurs: "In 1894 Lépine, in 1895 Mathias Duval applied the theory of amœboism to the intellectual phenomena. Dercum in 1896 adopted the same theory and ingeniously explained the phenomena of hysteria."

I take pleasure in sending you a copy of my paper, "Sur un cas d'hystérie à forme particulière" (*Revue de médecine*, July, 1894), from which you will see that it was not Dercum in 1896, but I, in 1894, who first proposed a theory of the phenomena of hysteria which had for its basis the neuron hypothesis. I hope that you will be so kind as to publish the present letter in your valuable journal.

R. Lépine.

30 Place Bellevue, Lyons, France.

STATURE AND INTELLIGENCE.

To the Editor of the Medical Record.

Sir In your editorial of October 13th, commenting upon "Degenerates in the Army," you ask whether it can be claimed that magnificent animal specimens of humanity are also as a rule endowed with a superabundance of brains. This brings up a most interesting yet puzzling anthropological study, full of contradictions.

From investigations among soldiers and from the literature of the subject, there is no doubt in my own mind that if a man's development is so unstable that he has psychical stigmata, he is invariably of bad physical development also and has numerous physical stigmata. As far as I know, there are few if any cases of abnormal minds in average bodies devoid of stigmata. It is a fair inference, then, that if a man's body is nearly an average in all respects, height, weight, proportions, etc., there must also be an average brain and therefore a normal mind—excluding, of course, normal men who have acquired insanity. Beyond this we dare not go, for there is absolutely no relation between intelligence and stature. Men of genius may be big like Bismarck or little like Napoleon or Da Costa, and the same may be said of the feeble-minded as well as of those of average intelligence. George Washington's physical measurements are said to have been identical with those of Jeffries the giant pugilist. Other illustrations might be given indefinitely.

It is true that the human brain weight depends upon the body weight, for many muscles require many brain cells. In like manner, the sparrow needs but a few grains of brain, while the whale and elephant must have more than man. Yet that indescribable and immeasurable variable called intelligence depends upon other things in addition to weight of brain, and the increase of brain weight due to increased stature consists of tissue which may not, and probably does not, have any bearing upon intelligence.

A big physique with immense reserve power and endurance is a decided element in forcing men to the front in the struggles of life. This is in accordance with recent investigations among Chicago school children which are said to show that the best scholars in any class are appreciably bigger than the rest. Hence other things being equal, the big men, having an advantage, should have a larger percentage of their number successful than the little men. Yet statistics show the very opposite, for Lombroso men-

tions ("Man of Genius," page 6) but twenty-six great men of tall stature, while he names fifty-nine who are short, some of them being even dwarfish or less than five feet in height. As the anomalies of height are equally distributed on each side of the mean, there must be some tremendously active cause to make the little men more than twice as brilliant as the big. The two classes, being equally removed from the average, should be equally abnormal mentally.

Among the big physiques of the army I have seen men of great intelligence and immense brain power or capability for work. This is of course the highest type of mind, and is in marked contrast to the sponge-like minds capable of great absorption but too flabby to work and produce. Nevertheless the big men of the army present a larger percentage of cases of arrested mental development, infantilism, feminism, etc., than does any other stature. This is one of the most curious facts in pathological anthropology, if I may so term this new science of the study of abnormal cases due to unstable development—the degenerates.

Men of little physique cannot enlist, so we cannot study them among soldiers, but moderate shortness of stature is no bar to a commission, and such are fairly numerous as officers. Taken all in all, the officers below the average of height are on an intellectual plane decidedly above that of the "magnificent animal specimens." They are both in a small minority, for the work of the army is almost wholly accomplished by men of average physique. As far as I have been able to determine, the decided majority of the great military leaders of history have been of average stature or decidedly less—even diminutive like Napoleon or frail like Wolfe. The gigantic Winfield Scott was an exception, but his tremendous egoism and innumerable blunders almost remove him from the list of great men in spite of his record from 1812 until 1848. So many of the "little fellows" of my acquaintance are excellent officers that I almost look upon diminutive stature as a military advantage for an officer.

Such a discussion need not be complicated by reference to specialized types of brain, capable of doing but one kind of work well and either accompanied by general intelligence or worthless in other directions. Such types are found in every stature and in every kind of physique, but the matter is too extensive to be enlarged upon here.

We cannot pretend to explain the alleged increase of the feeble-minded among the big men, but we can guess that it has some relation to that feeble-mindedness so characteristic of giantism and acromegaly. The pituitary is undoubtedly a growth centre, and is just as apt to be involved in unstable development as any other part of the body. If it is hypertrophied early, giantism results; if later in life, acromegaly, as Woods Hutchinson has shown. Sometimes in the early cases there is muscular increase alone, as in the "strong men," all of whom subsequently become as feeble as the giants and sooner or later show acromegalic signs. All of these big creatures are feeble-minded. The class of "magnificent animal specimens" of humanity may then contain some very able men who become renowned partly through the excess of animal energy, but it also harbors a large number of borderland cases, partially degenerate, overgrown through instability, and with a leaning toward the feeble mindedness of giantism. Can we not imagine that there is an organic basis for these cases in an abnormal pituitary?

Is it not a fact that college athletes noted for strength and size do not furnish as large a percentage of successes in life as the less robust, and simply because more of them are mentally below par? Joseph Chamberlain, in a speech at the opening of a gymnasium, is said to have confessed that he had never taken regular exercise in his life and rather disliked it. Are there not many other great or successful men ready to confess to the same physical laziness, no matter how energetic they may have been mentally? It is quite likely that the kind of intelligence needed for success does not run to athletics, nor is it found so much in the big men as in the little ones or the average sizes. Strong mental power must check bodily growth in some unexplained way through its influence on the pituitary—a theory which is fascinating, no doubt, but which of course cannot be proved.

Charles E. Woodruff,
Captain and Assistant Surgeon, U. S. Army.
Fort Riley, Kansas, October 19, 1900.

Gifts to a Hospital.—Mr. E. P. Wilbur, formerly president of the Lehigh Valley Railroad Company, has donated $10,000 to St. Luke's Hospital at Bethlehem, the income from which is to be used in maintaining the children's ward. Mr. Samuel Thomas, of Catasauqua, will build an operating-ward for the hospital at a cost of $10,000.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Proceedings of the Twenty-Sixth Annual Meeting, Held at Asheville, North Carolina, October 9, 10, and 11, 1900.

The association met at the Battery Park Hotel, under the presidency of Dr. Harold N. Moyer, of Chicago.

Addresses of welcome, on behalf of the city and State, and of the local profession, were delivered by Hon. Theodore F. Davidson and Dr. John H. Williams.

After the reports of the secretary, treasurer, committee on publication, etc., were read, the First Vice-President, Dr. A. H. Cordier, took the chair, and Dr. Moyer delivered the

Presidential Address.—He referred to matters of general interest to the profession. He dwelt at length upon an address which was delivered before the International Medical Congress by the distinguished American colleague, Jacobi, who saw fit to discuss the old code question. The speaker thought it unfortunate that this subject, long since dead but not buried, should be embalmed in the records of that congress. The medical profession of America did not need any apologist, but it did need, in his opinion, to apologize for the representative appointed to speak for it on that occasion. As to medical societies, there could not be too many of them. In no other country were these societies so numerous as in America. They were usually well attended. In foreign countries these societies were for the few; in this country they were for the many, and it was to their collective voice, speaking in no uncertain tones, that the profession owed the uplift of medical education. The speaker then discussed the relation of the medical profession to the law. The passage of medical acts had been urged by the medical profession, and physicians had been distinctly misunderstood in their attitude toward such legislation. Legislators felt that in some way the medical profession wished to put a fence around the practice of medicine, so that physicians, being on the inside, may fatten upon it. This was not true. Physicians urged the passage of medical-practice acts not for their personal aggrandizement, but simply for the protection of the people, to prevent the illegal practice of medicine by unqualified persons and by quacks.

Specialism.—If anything could be said in criticism of the medical profession in this country, it was the overweening inclination toward specialism. A physician should spend several years in general practice before adopting a specialty. Specialism had done many good things for medicine, but practitioners should see to it that it was not overdone. If a physician wished to acquire a broad general culture, it could come only from general practice. The selection of a specialty should, like matrimony, come naturally and without being forced.

Abdominal versus Vaginal Hysterectomy.—Dr. H. O. Walker, of Detroit, Mich., read a paper with this title. The question of the best approach surgically to the uterus and adnexa, he maintained, had evidently not been settled, judging from the amount of discussion of late upon this important subject. Cancer of the uterus was not an infrequent cause of death in women. The question of recurrence of cancer of the uterus was very important and was immediately connected with the method of its removal. The manner of recurrence of cervical carcinoma was either by extension into the broad ligaments, from the vagina downward and into other contiguous parts, as

the bladder and rectum, and occasionally to the body of the uterus, or by metastases through the lymph channels and by distinct direct implantation. The surgeon should be governed by the method of operation which would offer the best advantages in guarding against recurrence of the disease, and in order to illustrate this the author reported two interesting cases, one of which was a vaginal, the other an abdominal, hysterectomy. The report of one case showed what he could not have done by the vaginal method: the other portrayed what he could have done better, more safely, and more surely by the abdominal method. All things being equal, the abdominal route offered advantages that did not pertain to the vaginal route. First, the surgeon was better able to see what he was doing. Second, he was much better able to control hemorrhage by the abdominal than by the vaginal route when he was working in a dark cavity. There was less liability of slipping of the ligatures, and if they did slip they were got at more easily than by vaginal section. Third, the danger to the ureters was minimized, and if injured, the opportunity for repairing them was better, while if injured by the vaginal route the surgeon would have to do an abdominal section in order to effect their repair. Fourth, the prevention of sepsis was more certain by the abdominal than by the vaginal route, aided in the first instance by the Trendelenburg position, which gave opportunity for full protection of the intestines and peritoneum, while in the latter the opportunity for protection was limited, as it was an utter impossibility to secure perfect asepsis in the vagina when there had been long-standing infectious disease.

Cancer of the Uterus and its Treatment.—This paper was contributed by Dr. R. S. Sutton, of Pittsburg, Pa. Cancer operations, he stated, should be recommended not as curative, but as palliative, and therefore useful. Total vaginal extirpation of the uterus, at or after the time of the climacteric, should find a place as prophylactic treatment against cancerous disease. The paper consisted of a compact review of the anatomy, pathology, and present methods of treatment. The author expressed the opinion that treatment for existing cancer of the uterus had probably reached its complete evolution. In view of the ultimate results of this treatment, which he heartily indorsed, because there was none other known to take its place, he asked the question, *cui bono?* He then discussed the question of prophylaxis, and showed that the average age of the patients he had operated upon was forty-three years and a fraction, and he claimed that if these patients had all been subjected to total vaginal extirpation at the average age of forty years, all of them would have escaped cancer of the uterus. According to his own statistics, but four per cent. of the cases would have been fatal; whereas nearly one hundred per cent. of these patients did die within a period of two or three years after operations for cancer. He urged greater attention to the early repair of lacerations of the cervix, and a more painstaking observation and consideration by physicians at large of that train of symptoms preceding and leading up to the development of uterine cancer. He unequivocally recommended radical surgical treatment in all such cases, and clearly announced that if we were to diminish the number of cases of uterine cancer, and consequent mortality in the future, it must be done in forestalling the disease.

Dr. Edward W. Lee, of St. Louis, Mo., favored the abdominal operation in a large majority of cases. He believed it was easier to perform; the operator could see what he was doing; he had a more perfect control of the tissues, and could do a more thorough operation. The only cases in which he thought the vaginal operation was justifiable were those of small uncomplicated, fibroid tumors of the uterus that could be easily shelled out.

Dr. Chauncey D. Palmer, of Cincinnati, Ohio, said that until the past few years the vaginal method had been preferred to the abdominal. In cases of cancer of the uterus it was important to remove all of the diseased structure, consequently this could be more easily and thoroughly done by the abdominal than by the vaginal route. The causative relation between laceration of the cervix uteri and cancer of the uterus was so clearly defined that its importance ought to be recognized by all physicians.

Dr. J. Wesley Bovée, of Washington, D. C., mentioned three classes of cases in which vaginal hysterectomy for cancer of the uterus, with the removal of such other structures as might be involved, was advisable. In very feeble patients, who were not able to stand a prolonged operation, he favored the combined method advocated by Ries, Clark, Werder, and others. The combined operation had been done by him upon thirteen patients, all of whom were living, with two recurrences.

Dr. A. H. Cordier, of Kansas City, Mo., said that in cases in which there was extensive involvement of the cervix by the cancerous process, implicating the bladder and rectum, his patients had been much benefited by thorough curettage of the cancerous mass, followed by the use of the Paquelin cautery and packing of the parts with carbide of calcium. Along with this treatment he used the old Goodell vaginal injection of permanganate of potassium.

Dr. Hugh A. Cowing, of Muncie, Ind., urged upon the general practitioner the importance of making an early diagnosis of uterine cancer.

Dr. William F. Barclay, of Pittsburg, Pa., said that the general practitioner was to be censured to a certain extent for not referring cases of cancer of the uterus early enough to specialists. For years he had made it a rule, when in doubt as to the diagnosis of disease of the uterus, and when there was complaint on part of the patient, to refer the case to a specialist, and he had been satisfied with the result. The earlier operations were done for this disease the greater the prospect of prolonging life.

Post-Operative Internal Hemorrhage.—A paper on this subject was read by Dr. A. H. Cordier, of Kansas City, in which he drew the following deductions: 1. In diagnosticating post-operative hemorrhage, the history of the patient would aid much. 2. Symptoms of shock and those of hemorrhage were very similar. 3. In suspected cases a single stitch in the incision cut would tell. 4. In cases in which bleeding was anticipated, a tube should be used. 5. The surgery must be quick and decisive in these cases. 6. Large quantities of decinormal saline solution would save many cases. This should be used both per rectum and into the veins. 7. Strychnine, belladonna, etc., would not control bleeding from the uterine or ovarian artery any better than from the radial or temporal. 8. The surgeon should do what his surgical conscience told him was right.

Intermittent Hydrops of the Knee.—Dr. George W. Cale, of Springfield, Mo., reported the case of a woman forty-five years of age. The first appearance of her trouble began five years ago. There was no history of injury. There was a rapid accumulation of fluid in the left knee joint, which was not painful, however. This effusion disappeared in from one to four weeks, with or without treatment. The disease recurred at periods varying from one to six months.

Ventral Hernia Following Laparotomy.—This paper was read by Dr. E. Brindley Eads, of Chicago, Ill. The occurrence of ventral hernia as a sequence of abdominal section, he stated, was so common that it should command thoughtful consideration. The

author urged the adoption of those methods which personal experience had demonstrated to be of the greatest use, both immediate and remote. He quoted Greig Smith as saying that ventral hernia was a mere stretching of scar tissue, but the essayist regarded it as a stretching not only of the scar tissue, but of all of the tissues of the abdominal wall at the site of its occurrence. As intact, innervated muscular fibre was the only safeguard against hernia following laparotomy, the first rule was to make the abdominal incision parallel, or nearly parallel, with the direction of the motor nerves and of the most important muscular fibres supplied by these nerves. In considering the incision the following points must be taken up:

1. The length was largely dependent upon the thickness of the superficial fascia; it must be sufficient to allow free access to the muscles whose functional integrity was essential to success. 2. The length must be relatively greater than when muscular fibres were to be separated instead of divided. 3. It must vary with the pathological condition for which the operation was performed. 4. An opening of sufficient size must be made for thorough exploration and for securing the requisite degree of precision and rapidity in manipulation. 5. A long incision through the skin and superficial fascia did not predispose to hernia. 6. It lessened the mortality by providing ample space for the protection of surrounding viscera. 7. It lessened shock by diminishing the time required for the operation, and also the duration of the anæsthesia.

Several incisions were mentioned by the essayist. The difficulties he had experienced in reaching the appendix through the McBurney incision in acute suppurative cases of appendicitis had caused him to devise another method of approach in a more dependent part. This incision overlay the outer border of the cæcum, and led directly to the appendix. It was slightly curved outward and downward, crossing an imaginary line drawn between the anterior superior iliac spines. The centre of this curve was from an inch to an inch and a half to the inner side of the right superior iliac spine. The skin and superficial fascia were incised for about two inches. This freely exposed the aponeurosis of the external oblique, which was separated by means of the dry dissector, or the handle of a scalpel, in the direction parallel to its fibres, and well retracted. This brought into view the transversely arranged fibres of the internal oblique and transversalis muscles, and the twelfth abdominal, ilio-hypogastric, and possibly the ilio-inguinal nerves, which were in turn retracted in order to reach the transversalis fascia, which, together with the peritoneum, was divided transversely. The advantages gained by this incision were:

1. It provided easy access to the diseased area. 2. It enabled the operator accurately and securely to protect the peritoneal cavity from infection. 3. It lessened the liability to break down the inner limiting wall of adhesions. 4. It afforded a better opportunity to open the abscess cavity from the outer side. 5. It favored drainage. 6. It had not been followed in the author's experience either by appendicular fistula or post-operative hernia.

Gangrene of the Scrotum and Penis.—Dr. E. H. Richardson, of Atlanta, Ga., narrated the history of a case which showed the initial lesion to have been an abrasion of the skin near the os pubis, with, probably, infection by the erysipelatous cocci at this point, and later a mixed infection by the streptococcus of gangrene, terminating in the destruction of the gangrenous portion of the entire integument of the penis and of three-quarters of the scrotum. A plastic operation was made, with the result that the integument of the penis and testes was restored. The patient made a perfect recovery.

Tracheloplasty.—Dr. Henry P. Newman, of Chicago, read a paper on this subject. In order to maintain a condition of normal health in the body, he stated, it was necessary that all of the organs properly performed their functions. He called attention to the great importance of the function of the cervix uteri in relation to disease in women. In former times cervical lesions were recognized as a fruitful source of gynecic evils, and many operations and instruments were devised for their correction. Emmet's trachelorrhaphy, once so popular, had ceased to be adaptable to the needs of to-day in repairing cervices. Dr. Emmet, in conceding this himself and offering amputation as a substitute, stated that the great advance in the obstetrical art and the methods of caring for a lacerated cervix in labor had altered the character of surgical pathology, so that trachelorrhaphy, as formerly practised, was rarely called for. The author found the indications for plastic work upon the cervix still widespread enough to justify the presentation of a new method of operating. This he called tracheloplasty, it being plastic work designed not only to restore normal contour and relation, but to re-establish proper function. The distinctive features of the method were the use of a specially designed knife, the shape of the flaps in the anterior and posterior lips of the cervix, clean, smooth cut surfaces, accurate approximation of flaps, the certainty of restoring the proper lumen of the canal, and the simplicity of the after-treatment. Neither tracheloplasty nor any one operation of the kind should be relied on to correct all the ills which accrued from lacerations in childbed. It was frequently necessary to do such simple work as shortening the round ligaments, or suspensio uteri, when there was a displacement of the uterus; divulsion and curetting when disease had extended to the endometrium above; reparation of the pelvic floor when, through relaxation or trauma, there was a hernial condition of the rectum, bladder, vagina, or superimposed viscera; sometimes even the opening of the abdomen for plastic work, or resection of pathological conditions of the ovaries, tubes, etc. Any one or two of these accessory operations might be necessary to restore the patient, although the disease or deformed cervix might have been the essential, perhaps the sole, etiological factor in the case.

Middle-Ear Disease in its Relation to the Cranial Cavity.—Dr. O. J. Stein, of Chicago, read a paper on this subject, in which he pointed out the necessity of recognizing the importance of possible intracranial complications in every case of middle-ear disease. The various avenues of infection were dwelt upon at length, these being illustrated by beautiful drawings and specimens. The symptomatology of intracranial phlebitis, thrombosis, and abscess was discussed and several instructive cases were reported. In connection with this paper Dr. J. Holinger, of Chicago, gave an interesting stereopticon demonstration.

Nutrition and Stimulation.—This was the subject of the address in medicine delivered by Dr. I. N. Love, of New York City. Continuance of life, he said, beginning with the original protoplasm, the cell, depended upon proper nourishment. The recognition of this fact was essential in all the work of the physician. The proper nutrition of the new being, from the very beginning, prior to birth, should be assiduously looked after by the careful physician. After birth the security of the infant depended upon the due appreciation of its proper feeding. From infancy to maturity this should be the essential thought of the parent and the doctor, who should ever realize his importance as the helper of the parent in the building up of a complete man or woman. The entire scheme of tissue building, of repair, of maintenance of the mechanism of the human body, involved not only nutrition

but perfect elimination, and the two together were expressed in the term metabolism. Interrupted metabolism tended toward organic disease, and finally death. Perfect metabolism meant perfect health. Stimulants were of value if used in the right way and at the right time. In the healthful condition they were not needed; they were essentially a luxury. All luxuries should be used with the greatest care, and only the thoroughly healthy could indulge safely in luxuries. Stimulants were divided into two classes, namely, those that were exclusively remedial, and those that came under the head of luxuries associated with every-day life. Of all the stimulants, alcohol stood first. It was probably the most prompt diffusible stimulant we had. There were arguments for and against the thought that alcohol was a food. Coffee and tea were essentially domestic beverages, and while seemingly harmless they were potent whippers-up of energy and should be used with great care. Tobacco had never been thought of as a food. It was primarily a stimulant, but like all other stimulants it was secondarily a depressant. It was a luxury, pure and simple. Morphine, cocaine, and others of their class were of great value to the profession, but improperly used were more deadly in their effects than the scalpel in the hands of the unskilful.

The Treatment of Perirectal Abscesses.—Dr. John L. Jelks, of Memphis, Tenn., read a paper on this subject. Rectal abscesses, he stated, when properly treated, were not so serious as when it was the practice to use poultices and await pointing. These abscesses need not result in fistulæ, unless they were the result of malignant diseases, such as tuberculosis, cancer, and syphilis. The fault to be found with a simple incision and drainage of these abscesses was that their walls were not gotten rid of, hence this barrier to general infection or infection of other and deeper structures remained to continue an irritation and to cause suppuration. In many cases the abscess wall became calloused, and all efforts to establish granulation were futile. When he was able to elicit fluctuation, he opened freely and hastily irrigated through an irrigating-curette attached to a fountain syringe, until the irrigating-fluid came away free of débris; then with a sharp irrigating-curette he removed all of the abscess wall, thereby converting the cavity into a surgical wound. He used formalin solution in irrigating these cavities and packed them with iodoform gauze. After thus treating these cases he expected no further suppuration. Since using formalin solution in irrigating these cavities he had in the after-treatment of them seldom noticed any suppuration. Superficial abscesses should be dealt with in the same manner; or they may be frozen and excised as the surgeon would a tumor. They were, when otherwise treated, liable to infect deeper structures. Local anæsthesia would suffice, and curettage could be properly practised with it. If the wound was painful, or the formalin solution irritating even when very dilute, some other and milder solution would be indicated. In rectal surgery he had not found the objections to the use of formalin which had been referred to by rhinologists and laryngologists.

Simple Operation for Hemorrhoids: Enucleation.—Dr. J. Rawson Pennington, of Chicago, contributed this paper, which was profusely illustrated. He stated that he gave a cathartic the second night before the operation, a saline the following morning, and a bath and colonic flushing the night before. The next morning he gave an enema of from one-half to one pint of cool water, and operated two hours later. He emphasized the importance of carefully examining the entire rectum. He grasped each anal quadrant at the muco-cutaneous junction with a pair of forceps; the anus was everted, and the internal tumors were exposed. Seizing with the hand the forceps attached to the posterior quadrant, he fully everted it, and with a pair of scissors curved on the flat cut off the redundant membrane only, which was usually about one-third or one-half of the uppermost part of the hemorrhoidal node. This permitted the blood in the tumor to escape. All of the angiomatous tissue was carefully removed, when the remaining wall collapsed. Each quadrant in regular order was treated in a like manner. A stream of hot sterilized water flowed over the field continuously during the operation. Spurting vessels, if any, were caught with forceps and thoroughly twisted. Should this fail to control hemorrhage, he threw a ligature around the vessel and ligated it. The operation having been completed, he introduced a rubber-covered tampon which had been fully described in previous articles by the author. The advantages of this method were: There were no stumps to slough, no nerves were caught and squeezed, which would cause excruciating pain, as when the ligature was used; nor were the nerves and tissues burned to a crisp, as when the clamp and cautery were employed. The formation of a stricture was obviated. The patient was given a cathartic, and the tampon was painlessly removed at the end of forty-eight hours. There was no pain or bleeding with the movement of the bowels. After the bowels had moved, the patient was instructed to keep them soft for two or three weeks by taking compound licorice powder or Apenta water, the latter being very palatable and effective. He had performed this operation in fifty cases, with more satisfactory results than he had obtained by any other method.

Obstipation.—Dr. Sterling B. Taylor, of Columbus, Ohio, read this paper. Obstipation was defined, and a comparison of obstipation, constipation, and costiveness made. The causes of obstipation were dwelt upon and classified. Hypertrophy of the rectal valve was emphasized as the usual cause of obstipation. The essayist defended the views of Martin and his method. The symptomatology of the affection, and the palliative and radical treatment were discussed, the author closing his paper with the citation of several cases.

Tuberculosis of the Spine.—Dr. Alexander C. Wiener, of Chicago, contributed a paper on this subject. He made a plea for early diagnosis before deformity was noticeable. Extension and hygienic treatment were essential in avoiding complications, such as paresis and gravitation abscess. He exhibited a specimen which illustrated the possibilities of forcible correction of the spine. He narrated cases of psoas abscess in which he had effected a cure with injections of concentrated carbolic acid.

Medical and Surgical Treatment of Acute and Chronic Cervical Lymph Nodes.—Dr. Horace H. Grant, of Louisville, read this paper, in which the purpose and function of the lymphatic glands were dwelt upon. The author showed how they might be rendered useless and harmful by disease and disintegration. He pointed out the limitations of medical and expectant treatment, and outlined the indications for the various surgical procedures.

Fulminating Appendicitis.—This was the subject of the address in surgery, delivered by Dr. Charles A. Wheaton, of St. Paul, Minn. He said that every case of appendicitis was and by rights ought to be considered surgical, because the surgeon's training specially qualified him best to interpret the meaning of the symptoms encountered. Every case of so-called fulminating appendicitis should be operated upon as soon as its distinctive characteristics were known. High temperature and accelerated pulse, associated with local pain and rigidity, were strong presumptive evidences of malignancy in the attack, and if associated with vasomotor disturbances were practically proof

positive of perforation. The surgeon who refused the only chance that drainage might give even the most desperate cases was false to himself, and failed materially in discharging his obligations to his patient —obligations which the patient had a right to expect at his hands. A puncture in the median line, in the loins, or in a woman in the posterior cul-de-sac, under local anæsthesia, did not add to the danger of the condition, and it materially aided nature in the awful uphill fight. In short, in every fulminating case, the rule was to operate first, and philosophize afterward.

Subarachnoidean Injections of Cocaine for Operations Below the Diaphragm.—Dr. Carl H. Andersen, of Chicago, spoke on this topic. He referred to the work of Tuffier, Bier, and others in this comparatively new field, saying that sufficient credit had not been given to Leonard Corning as the originator and adviser of this method of anæsthesia. He described its technique, which was substantially that outlined by Tuffier, and reported six cases in which he had resorted to the method.

Case I.—Hydrocele, with vague history. The patient, colored, was twenty-eight years of age, strong and healthy. A subarachnoidean injection of ℥xv. of a two-per-cent. solution of cocaine was given. Anæsthesia was complete. When the scrotum was opened sarcoma of the testicle was found and removed. On the ninth day after the operation the patient died of pulmonary embolism.

Case II.—Varicose veins of the leg. An injection of ℥viii. of a two-per-cent. solution of cocaine was given. The anæsthesia lasted five hours and ten minutes. No pain was felt during the operation. Perfect recovery ensued.

Case III.—Trachelorrhaphy under cocaine anæsthesia. As soon as the operation was finished the patient fainted and remained in that condition for two hours. Under strychnine and salt water per rectum she rallied and recovered.

Case IV.—Amputation of a toe in a man seventy-two years of age. ℥vii. of a two-per-cent. solution of cocaine was injected. Uninterrupted recovery followed.

Case V.—Operation for suppurative appendicitis upon a woman. The operation was performed at 10 A.M.; at 2 P.M. the patient showed symptoms of medullary irritation, pain in the back, and severe headache. It was now several days since the operation was done, and the patient had had a terrific headache ever since.

Case VI.—Version and use of forceps. At the suggestion of Dr. Harold N. Moyer, Dr. Andersen injected ℥xvi. of a four-per-cent. solution of eucaine B in this case, with very satisfactory results. The patient suffered no pain whatever. Eucaine B could be perfectly sterilized by boiling.

Dr. Andersen spoke of the difficulties attending the sterilization of cocaine, and outlined a method by which this could be accomplished. He regarded lumbar puncture as a serious operation, and urged practitioners to be exceedingly cautious in employing it. These cases were reported for the express purpose of warning the profession that the method was far from harmless, and if it was employed indiscriminately it would lead to disastrous consequences.

Dr. Harold N. Moyer, in the discussion, said that if advised as to the use of this method of anæsthesia, he would say, Do not use it. No surgeon should undertake it unless he had a well-equipped laboratory. The method was at best in its experimental stage, and further research and experiments should be carried on in well-equipped clinics until the possible dangers of this method were better and more clearly understood. Among the dangers were the toxic properties of the cocaine. A four-per-cent. solution of eucaine B could be used with absolute safety. It was about one-third as toxic as cocaine, and one-half as anæsthetic as cocaine, but it could be absolutely stezilized. The danger of infection from such injections was considerable, and should not be overlooked. As to the remote dangers from this form of anæsthesia, cases had not been observed sufficiently long to enable surgeons to say whether or not there were such dangers.

Treatment of Tuberculous and Purulent Hip-Joint Disease with Large Speculum Drainage and Pure Carbolic Acid.—Dr. A. M. Phelps, of New York City, read a paper with this title. All abscesses, tuberculous or purulent, he maintained, should be opened for the purpose of exploration as soon as the diagnosis was made; secondarily, for drainage, and for any surgical procedure which might be deemed advisable. Excisions should be performed when the acetabulum was extensively diseased, the diseased tissues removed, and the joint thoroughly washed out with pure carbolic acid, then with pure alcohol, and finally with a two-per-cent. solution of carbolic acid, and as large a drainage tube of glass as the wound would take should be inserted. Through this large drainage tube the packing for drainage purposes could be made. The large glass speculum enabled the operator to watch every pathological change which took place throughout the wound. It kept the soft parts widely separated, and prevented their union until after the bone had granulated up and healed. It enabled the operator to dress his patient without doing violence to the granulating surfaces of the wound and inflicting unnecessary pain. All rubber drainage tubes should be entirely discarded, as they were filthy, collapsible, and a source of infection. The carbolic acid was absolutely neutralized by the action of the alcohol. Local carbolic poisoning, and even when the drug was taken internally, was neutralized by the action of the alcohol. Pure carbolic acid applied locally was a specific for erysipelas, the points of which were brought out in the paper.

Pulmonary Tuberculosis in Infancy and Childhood.—Dr. Frank P. Norbury, of Jacksonville, Ill., read this paper. This disease, he stated, was not a rarity among children, as the utilization of available post-mortem material showed. Heredity was of etiological importance, but it had lost its prestige as compared to its former standing. Modern scientific inquiry has shown that infection was the etiological factor *par excellence*. Direct heredity could account for a limited number of cases. The infection theory was proven by the lateness of the appearance of disease; few cases occurred during the first year of life, and the number steadily increased thereafter. The mode and route of infection were important considerations. Northrup, Carr, and others had shown that tuberculosis started more frequently in the thorax than elsewhere. Pulmonary affections, such as whooping-cough, influenza, etc., created favorable conditions for infection. Enterocolitis and gastro-enteritis created portals for intestinal infection. Milk was a source of infection, and so was tuberculous meat. The diagnosis might be confounded with that of malnutrition. Bovaird stated that two evidences of early invasion were "progressive emaciation, not explained by other disease; continued elevation of temperature similarly conditioned." The differential diagnosis from broncho-pneumonia could be made only by laboratory methods. Acute miliary tuberculosis and broncho-pneumonic tuberculosis were most frequently found in infants and children. The complications were meningitis, empyema, and involvement of bones. The prognosis was grave in almost all cases, but lesions of the lungs might heal under favorable conditions. With reference to treatment, prophylaxis during infancy should include attention from birth if the mother was tuber-

culous; also good hygiene, open-air treatment, and climatic change when possible. The symptomatic care should be the same for children as for adults. Good nutrition should be maintained, and as little medicine given as possible. Creosote was recommended by the author, as were simple tonics.

The Physician as a Sanitarian.—Dr. Hugh A. Cowing, of Muncie, Ind., read a paper on this subject in which he discussed preventive medicine; hygiene of infection; the physician as a factor in the spread of infection; the physician and the health officer; health legislation; and the physician and the public schools.

The Philosophy of the Science and Art of Medicine.—By Dr. William F. Barclay, of Pittsburg, Pa. The author said that thoughtful minds should be engaged in sifting truth from falsehood. True and false philosophy should be appropriately applied to results obtained in rational conclusions. The philosophy of medicine was the comprehension of the truth in the investigation of the science, enabling one to arrive at rational conclusions in the study of physical laws which governed organized matter under normal and pathological condition.

Asthma.—By Dr. B. Alexander Bate, of Louisville, Ky. The author stated that Loomis, Trousseau, Salter, and others had considered asthma a diathetic neurosis. Haig attributed it to the effect of uric acid upon the circulation in the thorax. Modern opinion seemed to regard asthma as a neurosis of the pulmonary plexus due to arthritism. In bronchial asthma uric acid in the blood so altered nutrition as to cause a neurosis of the branches of the pulmonary plexus, thus inducing hyperæsthesia and engorgement of the bronchial mucosa, spasmodic contraction of the muscular fibres, and the various manifestations of metabolism. Asthma frequently alternated with such diseases of the arthritic diathesis as neuralgia, migraine, angina, and gout. Clearing the blood of uric acid had relieved asthma, only to be followed by gout, as the uric acid was precipitated into the tissues. Asthma might be said to belong to the class of uric-acid diseases due to the effect of high arterial tension, in contradistinction to those produced by precipitation of urates into the tissues. The attacks came on most frequently when the blood was loaded with uric acid during the alkaline tides. The causes of asthma were divided into two classes: First, the systemic or essential cause—the arthritic diathesis. Second, the local or exciting cause of the attack. The first of these was perhaps present in every case. Cases were recorded in which mediastinal tumors, pressing upon the pneumogastric nerve continuously, first caused asthmatic paroxysms during the alkaline tide. Pressure explained the neurosis, and the time of the paroxysm manifested the uric-acid factor. The second class of causes could act only when the first desisted. The exciting causes of the disease were mentioned, also the symptoms. Modern treatment had been able to cut short the attacks in most instances, and often to prevent their return. Prophylactic treatment should embrace proper hygiene and diet. Prophylaxis should be begun in the children of lithæmic individuals. The therapeutic measures embraced the care of the attack and treatment during the interval. After the removal of the exciting cause the treatment consisted in the use of such remedies as overcame arterial tension by freeing the blood of uric acid. The treatment of the interval consisted in the use of such drugs as eliminated uric acid from the system, and the adherence to such a diet as permanently kept down arterial tension. Rational treatment, based upon the theory of uric-acidæmia as the chief factor in the production of asthma, had been most satisfactory in the hands of the essayist.

The Curability of Inebriety by Medical Treatment.—Dr. T. D. Crothers, of Hartford, Conn., stated that inebriety was a neurosis, usually self-limited, and very largely curable. The craze for drink was symptomatic. The real causes were central nerve irritation, exhaustion, poisoning, and starvation. The success of the treatment depended upon accurate knowledge of the causes and conditions present in each case, and the accurate application of general means and measures for their removal. Each case required special means and measures particularly adapted to meet the conditions present. The family physician as well as the specialist should treat these cases successfully.

Further Observations on the Clinical Application of the Suprarenal Capsule.—Dr. W. H. Bates, of New York City, read a paper with this title. The author regarded the aqueous extract of the suprarenal capsule as the most powerful astringent, hæmostatic, and heart tonic known to the profession. It lessened congestion of the eye and of other organs. The extract was not irritating or poisonous, and, unlike other powerful drugs, was never in his opinion contraindicated. In short, the profession had no remedy which was so useful in all forms of inflammation.

Clinical Value of Purgative Mineral Waters.—Dr. Edwin Rosenthal, of Philadelphia, discussed this subject. He spoke of natural and artificial mineral waters; simple, thermal, common salt, or muriated waters. He dwelt upon the waters mostly met with in commerce, spoke of their chemistry, names, mode of action, uses, method of selection of a special purgative water, etc.

What the Law Requires of a Surgeon.—Dr. Dudley S. Reynolds, of Louisville, Ky., followed with an interesting paper on this subject. A surgeon, it was stated, must possess a reasonable familiarity with the science of his profession; he must exercise reasonable skill for the locality in which he practises, and must devote due diligence and care in attending to his patient. If the patient declined to submit to that treatment which in the judgment of the surgeon was most appropriate, and he did not abandon the case at once, he assumed liability for the result of failure to do that which in his judgment was best for the relief of the patient.

Differential Leucocytosis.—Dr. L. H. Warner, of Brooklyn, N. Y., read this paper. Experiments in recent times, he held, had given us a better insight into leucocytosis. It had been demonstrated to be due to three causes—digestion, inflammation, and infection. Physiological and biological experiments had proven that by means of medication a true picture of leucocytosis might be produced, but which in reality represented leucocyto-diuresis — a condition very desirable in the treatment of disease and a recognition of which was of the greatest value when hæmatology was called upon to aid in arriving at a correct diagnosis.

The following officers were elected for the ensuing year: *President*, Dr. A. H. Cordier, of Kansas City, Mo.; *First Vice-President*, Dr. Charles F. McGahan, of Aiken, S. C.; *Second Vice-President*, Dr. Charles L. Minor, of Asheville, N. C.; *Secretary*, Dr. Henry E. Tuley, of Louisville, Ky., re-elected; *Treasurer*, Dr. Dudley S. Reynolds, of Louisville, Ky., re-elected.

Put-in-Bay, Ohio, was selected as the next place for holding the meeting; time, September 10, 11, and 12, 1901.

Dr. J. C. Culbertson, of Cincinnati, Ohio, was selected as the chairman of the committee of arrangements.

The meeting ended with a banquet at the Battery Park Hotel, given by the Buncombe County Medical Society.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, October 8, 1900.

CHARLES N. DOWD, M.D., CHAIRMAN.

Recovery from Strangulation of Intestine Due to Meckel's Diverticulum.—DR. JOHN F. ERDMANN presented a man, thirty-four years of age, first seen by him in consultation on May 1st. On April 29th he had been seized with severe abdominal pain, which had become localized in the region of the appendix on the following day, and had been associated with the presence of a tumor. On incision, a large Meckel's diverticulum had been found adherent to the appendix and strangulating the bowel. The appendix was removed, and inverted before suture. With the exception of a stitch abscess recovery had been uneventful.

Some Cases of Acute Appendicitis.—DR. ALEXANDER B. JOHNSON read a paper with this title (see page 688).

Glass Drainage Tube Broken off in the Pelvis.—DR. HOWARD COLLINS spoke of the usefulness of a sponge-holder and gauze in cleansing out the pelvis. When the opening is deep, the cotton should be placed in the holder flat, and then on moving the holder up and down the suction would tend to open up small abscess cavities in the neighborhood. Reference was made to a case in which a long glass drainage tube had been inserted into the pelvis and had been broken off by the patient while delirious. A sharp fragment of the glass had pierced a large blood-vessel, giving rise to all the symptoms of shock from loss of blood. The patient was transfused, and then the tube was removed after considerable difficulty.

DR. JOHN A. WYETH heartily concurred in the statement made in the paper regarding the harmfulness of evisceration or undue handling of the bowel. In cases of purulent peritonitis associated with foul pus, irrigation with hot salt solution offered the best, if not the only, hope of recovery. It was quite important in such cases to use the irrigating-fluid under considerable pressure, and to do this he placed the irrigator at a considerable height. He also laid great stress upon the wiping-out process, because he believed it to be very detrimental to leave moisture behind. He was particularly careful to clean out the space behind the ascending colon. He had always feared to make use of the glass drainage tube in the pelvis, although he had not before learned of any such accident as that mentioned by the last speaker. When drainage was employed he made use of the wick drain.

DR. W. K. OTIS said that he had witnessed a number of the operations described in the paper, and could testify to the fact that at least the larger cavity of the peritoneum was involved in the cases described as examples of general purulent peritonitis.

DR. A. ERNEST GALLANT asked if in the cases of abscesses in the pelvis mentioned in the paper there had been free pus or accumulations behind the peritoneum. He had himself seen these cases of retroperitoneal accumulations end in recovery, though slowly. A few days ago he had operated upon a case in which the appendix was up against the abdominal wall. During the manipulations incident to removal, he had broken through the cæcum into one of these retroperitoneal abscesses. He had been surprised in this instance that the pus was not of the stinking kind usually found in pelvic abscesses. He had had this man under observation for about four years because of syphilis, and this had suggested to him the possibility that this abscess had resulted from the breaking down of a gumma. In two cases he had secured good drainage by an incision through the vagina.

DR. JOSEPH WIENER, JR., remarked that at the very last meeting of this section, a few months ago, the general trend of discussion had been against the use of saline irrigation, and yet we had just heard of excellent results from such irrigation. It was certainly very important to dry out the peritoneal cavity before the wound was closed, but whether it was better to be content with simply drying it out or to use first saline irrigation, he was as yet undecided. In the cases in which colon bacilli predominated the prognosis was best; the next best were those in which staphylococci were found, whereas the worst prognosis was in those of streptococcus infection. Subphrenic abscesses developed almost invariably in cases of peritonitis, and were probably the result of lymphatic infection.

DR. WYETH asked if there was any difference in the odor of the pus in the different varieties of infection.

DR. WIENER replied that in the cases characterized by the foulest pus the colon bacilli predominated.

DR. ROBERT T. MORRIS was of the opinion that the intravenous infusion of large quantities of physiological salt solution constituted an effective method of eliminating toxins and combating sepsis. According to his experience the foulest-smelling cases were not the gravest ones, but they were associated with the colon bacilli. Concerning drainage he would say that Clark's classical article of three years ago on the subject of drainage by way of the peritoneum should be carefully read by all surgeons. He was very glad that at the present day there was a greater tendency toward using smaller incisions and depending more upon the well-known capacity of the peritoneum to dispose of fluids. In some cases of several days' standing and having symptoms of sepsis, he had been surprised to find the pus sterile; hence the operator must be cautious about distinguishing between cases which must be drained, and those which could be safely closed without drainage. He predicted that surgeons would be surprised in the future to find what could be accomplished without drainage.

DR. JOHNSON, in closing, said that in his cases of abscesses in the pelvis the pus lay among the viscera in and not behind the peritoneum. He was convinced that the less mechanical violence was done to the peritoneum, and particularly to the intestine, the better for the patient. It had been shown that the reaction to mechanical irritation was greater in proportion to the degree and extent of inflammation present. For this reason he preferred the method of placing gauze in the cavity to the plan of wiping it out with gauze. He had laid great stress upon the harmfulness of evisceration because in conversation with an eminent surgeon in this city the latter had told him that he practised that method, and did so because he thought this shortening of the operation was in itself a life-saving measure. The prognosis did not by any means depend solely upon the kind of bacteria present; many other factors must be taken into consideration.

Some Considerations on Abdominal Section.—DR. HOWARD COLLINS read this paper. He said that when a choice of incision was practicable, the one selected should be that which least interfered with the supporting function of the abdominal wall. Loss of continuity of the normal structures and the paralysis of the muscles from division of their nerve supply were important contributing causes in the production of hernia after operation. The most important nerves were the lower dorsal. They emerged from under cover of the ribs and passed obliquely downward, forward, and inward until they reached the outer margin of the rectus. They then divided into two branches, one passing inward and slightly upward, and the other inward and slightly downward. From a point half an inch below the tip of the last rib a line should be drawn to the spine of the pubis of the opposite side. This line

from the point of origin to the outer margin of the rectus muscle overlay the twelfth dorsal nerve. A similar line drawn from a point half an inch above the tip of the twelfth rib to the middle of Poupart's ligament on the opposite side marked the eleventh nerve. A line starting half an inch in front of and above the tip of the eleventh rib, and extending to the anterior superior spine of the ilium on the opposite side, traced the course of the tenth nerve. The ninth nerve lay between the ninth and tenth ribs. It split into two branches at the edge of the rectus, midway between the entrance of the eighth and tenth nerves. The speaker said that for this method of mapping out these nerves he was indebted to Dr. Brewer. The nerves supplying the recti muscles lay at a right angle to their fibres, and hence mere splitting of the recti did not do away with the chance of dividing these nerves, but only a few small fibres were likely to be cut. Instead of cutting through the fibres of the semilunaris he suggested making the incision just external to this point, as this went through tissues having sufficient thickness to enable one to secure better union. In the operation for extirpation of the kidney, a good incision was one starting one inch below the last rib and extending from the quadratus lumborum to the rectus muscle. This traversed no important nerves. A vertical incision through the substance of the right rectus muscle, about one inch from its outer border, gave a most favorable entrance in gall-bladder cases. McBurney's intermuscular incision was commended highly except for cases requiring drainage. Here it was not desirable because of the tendency of such an incision to close. He had heard of a case in which the intermuscular incision had been used in making an artificial anus. In that case it was reported that the muscular opening fulfilled very well the function of a sphincter.

Dr. Moschcowitz said that with the so-called Kammerer incision the nerves usually passed across the incision. When first using this incision he had divided one or more of these nerves, but subsequently he had read an article in which the statement had been made that the nerves could be divided and sutured again very satisfactorily, even though the suturing were done very rudely. Further experience had taught him that it was ordinarily possible simply to dislocate the nerve, and that when this precaution was taken hernia rarely followed the operation.

New Clavicular Crutch.—Dr. Carter S. Cole presented this splint, which was founded on one used by the late Dr. C. Fayette Taylor in connection with his spinal brace. It consisted of a connecting steel bar, adjustable as to its length, and having at either end a hard-rubber pad of such shape as to take the place of the clavicle. Round leather pads, kept apart by a band of steel, were adjusted over each shoulder blade, and the two parts of the apparatus were held together by webbing straps. The original Taylor instrument was not intended for the treatment of fractured clavicle, but was a mere adjunct of the spinal brace. In the instrument presented, adequate provision was made for the accurate adjustment of the anterior pads or "false clavicles." Dr. Cole said that he had made use of many other varieties of splints and dressings for fracture of the clavicle, and they had all proved quite unsatisfactory until he had devised this one.

Intestinal Anastomosis—Connell Suture.—Dr. Thomas H. Manley reported a case of strangulated hernia first seen by him at the Harlem Hospital on August 20th. At that time there had been no signs or symptoms to indicate that the hernia was a complicated one. Operation had been done immediately, and the sac found filled with foul-smelling fluid, and the gut gangrenous. The affected portion of intestine extended up to the cæcum. About 40 cm. of intestine were resected, and on division of the bowel the latter was found to be filled with blood. Deep interrupted Lembert sutures were used. The ileum was implanted on the anterior wall of the cæcum. The operation for radical cure of hernia was also done, but the wound was left open. On the sixth day the discharge from the wound had a fæcal odor, but after the second week this ceased. At present the patient was in excellent condition, having completely recovered. The section of the bowel was made with a long slope, with the object of maintaining the circulation up to the tip. The Connell suture was employed—a continuous suture passing through all the layers. It was the most rapid method of its kind that he had ever tried. Emphasis was laid upon the technique used in making the lateral anastomosis.

Choledochotomy.—Dr. J. A. Blake reported a case of choledochotomy and presented the specimen. According to the history, the first attack of colic had been only four months previously, and had resulted in collapse and loss of consciousness. The patient had several attacks associated with jaundice while in the hospital. For the last two months before operation there had been chills and fever. At the operation the gall bladder was found very much contracted, but it contained no stone. Palpation of the common duct revealed the presence of a stone. It was used as a splint for the insertion of the sutures and preventing the escape of bile. Eight fine silk sutures were used, and by this plan were quickly inserted. The incision was made through the rectus muscle. The drainage tube had been removed on the fifth day. At no time was any bile-stained fluid discharged, and the healing-process proceeded most satisfactorily.

Therapeutic Hints.

Tonsillitis.—At the onset of acute catarrhal tonsillitis give a saline purgative, and spray or brush the tonsils every hour with—

℞ Formalin ..... ♏ xv.-xx.
Potass. chlor ..... ʒ i.
Liq. ferri. chlor ..... ʒ i.
Aquæ menthæ pip ..... q.s. ad ʒ iv.

And give—

℞ Quininæ hydrobromat ..... gr. i.
Sodii benzoatis ..... gr. ij.
Salol ..... gr. v.
M. et ft. cap. No. i. S. One every three hours.

—J. A. Abraham.

Tapeworm.—

℞ Pomegranate bark of root ..... ʒ iv.
Pumpkin seed ..... ʒ i.
Ext. male fern ..... ʒ i.
Pulv. ergot ..... ʒ ss.
Croton oil ..... ♏ ij.
Gum arabic ..... ʒ ij.
Water ..... ad ʒ viij.
M. S. At one dose.

A light supper, a full dose of Rochelle salts.

In Bacteruria.—Lavage and instillations of nitrate of silver, sublimate, or protargol, combined with the internal administration of salol in increasing doses up to ʒ iiss. per diem. Large quantities of water. —Jeanbrau.

When streptococci predominate, antistreptococcic serum—Dewy.

Urotropin in Typhoid Fever.—During the first two weeks of typhoid fever bacilli can be obtained from the fæces, but they gradually disappear during the third

and fourth weeks. On the other hand, the urine is free from bacilli in the early stage of typhoid, and they appear during the third or fourth week or during convalescence. Both excreta are a source of reinfection. Dr. P. Horton Smith recommends urotropin in doses of 2 gm. daily, and claims that under its use the bacilli disappear.—*British Medical Journal.*

Cholera Morbus.—Very hot turpentine stupes, consisting of one tablespoonful of turpentine to the quart of water, and internally—

℞ Spir. æther. comp.,
Spir. lavandulæ comp.,
Tinct. opii camph ..... āā ʒ ij.
Tinct. capsici ..... ♏ xv.
Tinct. zingiberis ..... ʒ ij.
M. S. One-half to one teaspoonful every two hours.

—S. A. Buchanan.

For Earache.—

℞ Carbolic acid ..... gr. vij.
Fld. extract of opium ..... ♏ vi.
Hydrochlorate of cocaine ..... gr. iij.
Atropine sulphate ..... gr. iij.
Water ..... ʒ i.
Gelatin ..... gr. xviij.
Glycerin ..... ʒ iiss.
M. et ft. bougies No. xlii. S. Insert in ear.

N.B. Keep in glass bottle and dust with lycopodium.
—G. L. Richards.

Barber's Itch.—

℞ Ichthyol ..... gr. xx.
Sulphur precipitat ..... ʒ i.
Bismuth formic iodide ..... ʒ ss.
Vaseline (benzoinated) ..... ℥ i.
M.

—Buchanan.

Scarlatinal Angina.—

℞ Sozoiodol-sodium,
Sulphuris precip ..... āā 15
M. S. Insufflate with powder blower several times daily.

When insufflation causes nausea the sozoiodol-sodium may be given internally in solution in half-teaspoonful doses three times a day.—A. Baginsky.

In Chronic Prostatic Hypertrophy, suprarenal extract in five to ten grain doses three times a day after meals is recommended.

In Eclampsia, if the spasms are apparently under control and yet the pupil is contracted, anticipate a return of the spasm.—*Medical Summary.*

Ptyalism.—

℞ Sodii boratis ..... ʒ ij.
Pulv. myrrhæ ..... ʒ i.
Aquæ ..... ℥ vi.
M. S. Mouth wash.

—Potter.

In Acute Bronchitis.—

℞ Ammon. muriat ..... ʒ i.
Liq. ammon. anisatis ..... ʒ iiss.
Tr. opii camph.,
Tr. hyoscyami ..... āā ʒ iij.
Syr. pruni virgin ..... q.s. ad ℥ ij.
M. S. ʒ i. every three hours.

Purpura.—

℞ Sodii sulphatis ..... ʒ ij.
Ferri sulphatis ..... gr. iij.
Ac. sulphurici dil ..... ♏ xv.
Tr. hyoscyami ..... ♏ xl.
Infus. calumbæ ..... ℥ ij.
M. S. To be taken every morning.

—Tanner.

Schoull's Treatment for Pulmonary Tuberculosis.—For ten successive days, mornings (sometimes evenings also) Schoull gives subcutaneous injections of 0.05 gm. of sodium cacodylate; then intervenes a pause of ten days; meanwhile and for fifteen successive days he gives internally, after meals, 0.5 to 1.0 gm. of thiocol in powder form. This is followed by a five days' pause, and the cycle is then repeated.—*Journal des Praticiens*, August 18, 1900.

In Syphilitic Lobar Pneumonia.—

℞ Ammon. iodidi ..... gr. xl.
Spir. ammon. aromat ..... ʒ ij.
Elixir aromat ..... ʒ i.
Aquæ ..... q s. ad ℥ viij.
M. S. ʒ i. t.i.d.

In Pelvic Inflammation.—Liquor hydrargyri perchloridi in half-drachm doses three times a day, combined with infusion of calumba, often exerts a marked influence in the absorption of inflammatory products, and is, in my experience, the simplest and most successful drug in cases of prolapse of the ovary, with adhesions.—Bedford Fenwick.

In Pulmonary Tuberculosis.—

℞ Calcii phosphatis,
Menthol ..... āā gr. iv.
Sodii bicarb ..... gr. iij.
Pulv. nucis vomicæ,
Ferri lactatis ..... āā gr. ¾
M. S. One such dose to be taken four times daily.

In Acute Rhinitis.—

℞ Ichthyoli 0.05
Ætheris 50
Alcohol 50
M. S. Use as a spray.

In Acne due to Digestive Derangement.—Internally:

℞ Creosoti ..... ♏ ss.
Cerii oxalatis ..... gr. ij.
Pepsini pur ..... gr. i.
Strychninæ sulphatis ..... gr. 1/60
Tinct. belladonnæ ..... ♏ ij.
Podophyllotoxini ..... gr 1/10
M. et ft. cap. No. i. S. One such to be taken after each meal and at bedtime if necessary.

Locally:

℞ Acidi salicylici ..... gr. xx.
Olei eucalypti ..... ♏ x.
Acidi borici ..... ʒ ss.
Ungt. zinci oxidi,
Ungt. aq. rosæ ..... āā ʒ ss.
M. et ft. ungt.

—Shoemaker.

Furunculosis of the Ear.—

℞ Zinci oxidi ..... ʒ i.
Acidi carbolici ..... gr. x.
Vaselini albi ..... ʒ i.
M.

A cylindrical tampon of cotton-wool is smeared with a layer of this ointment, and inserted into the canal. It should be large enough to produce considerable pressure. The greater the swelling the greater should be the pressure exerted by the tampon. The pain is at first severe but disappears after a few moments, if not insert smaller tampon. Before tamponing douche canal with lysol solution. Repeat tampon and douche daily.—Lamel, Oxel and Muller.

Flatulence and Colic in Infants.—

℞ Magnesii carb ..... gr. iiss.
Rhei pulv ..... gr. ¼
Syr. zingiberis ..... ♏ v.
Ung. menth. pip ..... q.s. ad ʒ i.
M. S. Given every two to four hours to an infant three or four months old.

—Ashley and Wright.

Cathartic Lemonade.—

℞ Sodii phosphatis ..... ʒ viss.
Spir. limonis ..... ♏ xx.
Syr. simplicis ..... ʒ ij.
Aq destill ..... q.s. ad ℥ x.
M. S. Take at a dose.

A Study of the Physiological Action of Phenacetin.—1. Moderate doses of phenacetin are without any distinct action on any vital organ. 2. Large doses

lessen reflexes by a direct action on the spinal cord. 3. Doses of 0.5 gm. per kilo. of body weight (a little less than one ounce for a one-hundred-and-fifty-pound man) kill by arrest of respiration. 4. Doses even up to 0.5 gm. per kilo. have no distinct effect on the circulation.—H. C. AND H. B. WOOD.

Hyperidrosis Pedis.—

℞ Balsam of Peru	1
Formic acid	5
Chloral hydrate	5
Alcohol, absolute	89

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 27, 1900:

	Cases.	Deaths.
Tuberculosis	237	160
Typhoid fever	140	32
Scarlet fever	91	5
Measles	46	4
Diphtheria	226	37
Laryngeal diphtheria (croup)	9	4
Cerebro-spinal meningitis	0	6
Varicella	2	0

Quinine in Malaria.—Dr. Manson in the discussion held on the use of quinine in malaria at the recent meeting of the British Medical Association, spoke as follows: "The reputed prophylactic action of quinine is but a phase of its therapeutic action, it is the application of the drug to the parasite, and not an immunizing of the body against the entrance of the parasite we have to deal with, therefore we may confidently expect that if it will cure a malarial affection it will prevent the development—the development though not the introduction of the germ. Further, that as some types of the parasite are highly amenable to the drug given therapeutically, similarly its prophylactic power will be greater against such, thus we may confidently expect it to be a timely prophylactic as against the benign tertian, but less active against the malignant tertian. The value of the drug is apt to be underrated in consequence of its being given in too routine a fashion, and often under conditions in which it cannot be absorbed as in states of severe gastro-intestinal catarrh. Such failures should be eliminated in assessing its prophylactic value. I should recommend that, in future, experiments in prophylaxis be made with the aid of the microscope, and in reference to the particular type of malarial parasite it is used against, and also that the gastro-intestinal condition of the individual experimented on be investigated and recorded."

Origin of Syphilis.—It has always been a moot question to know whether syphilis was of American or of European origin. Dr. Zambaco Pacha, who has become quite an authority on such subjects as leprosy, Morvan's disease, and kindred affections, has presented some photographs of bones that had been found in Upper Egypt, and dating from eighty centuries back. These bones showed indications of suppurative osteitis, enlargement of the femurs, tibias, and fibulæ. The disposition of the lesions is such that Professor Lannelongue admitted that they seemed to be of syphilitic origin. This would prove that syphilis has existed in Europe from the first ages. Dr. Fournier examined the photographs and declared that there was no sure sign that the lesions were of syphilitic origin. The simple examination of a bone is not sufficient to demonstrate the existence of syphilis. The common varicose ulcer sometimes causes hyperosteosed tibias, which are similar to those caused by syphilis; the same can be said of typhoid fever. Dr. Zambaco insisted on the large number of lesions seen, but Dr. Fournier said that tuberculosis sometimes produced similar results.—Paris correspondent *Therapeutic Gazette*.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended October 27, 1900:

		Cases.	Deaths.
SMALLPOX—UNITED STATES.			
Colorado, Arapahoe Co	September 17th to October 10th	9

Water Supply in Military Camps.—Major James, R.A.M.C., read a paper before the British Medical Association at their recent meeting in Ipswich on sanitation in military camps; part of the address was as follows: "The water supply is one of the most important things to supervise, and most of the commonest camp pests in the shape of enteric fever, dysentery perhaps, and cholera, are water borne. Water which

may be good at its source may so easily become poisonous between that and the consumer's stomach, that the distribution must be as closely watched as the origin, and this in camp is a great difficulty. When men are thirsty they will drink anything and anywhere; I believe something could be done by education to restrain a man at ordinary times, but when the weather is hot and water scarce, reason has to give way to impulse. If, however, water is plentiful and good, and obtained from a stream, a spot above the camp should be marked for drinking; lower down for horses, and lower for washing and washing clothes. The point of obtaining the drinking-water should be policed, and the stream above put out of bounds, and the area draining into it also. The water should be delivered from a spout or pump, and no dipping of vessels into it allowed. It may be dammed up so as to accumulate and allow sediment to fall, and if the camp be standing there sheltered or roofed over. In the case of water being obtained from a large river it should be rough filtered, or a Norton's tube pump sunk in the shore to stop out the grosser impurities, then boiled or filtered or both. The use of alum to throw down suspended matter is universal among Chinese on the Peiho and might take the place of rough filtering as a prelude to boiling, etc. For use in the men's water bottles, tea should be made on a large scale where water is not above suspicion. A sterilizer with a coiled tube heated at one point was, I believe, tried but is not yet very portable. The use of aërated water or the water obtained at the authorized source may be encouraged. Where the camp is a standing one it may be possible to dig wells. This should be done if water is near the surface and the alternative source is a stream liable to pollution."

The Smoke Nuisance.—At the International Congress of Hygiene and Demography recently held in Paris, Mr. Adolphe Smith, in the discussion which followed a consideration of the smoke question in towns, had this to say: "He protested against the suggestion sometimes lightly made that smoke was not injurious. Parisians especially would have to be careful now that wood was so dear, and the consumption of coal in private houses was increasing rapidly. There was much more smoke in Paris, and even if this smoke was not particularly injurious in itself, it became very mischievous when mixing with a white mist it produced a black fog, and the fogs in Paris were getting more and more like those in London. Whatever chemists might say about smoke, it was a fact that in London thick 'pea soup' fogs sent up the death rate by leaps and bounds. As for the suggestion made that the law should insist on perfect combustion—what was perfect combustion? Theoretically, if perfectly consumed, a kilogram of carbon should yield 8,080 calorics of heat and produce no smoke whatever and no carbon monoxide. Practically a kilogram of carbon yielded little more than 2,470 calorics of heat, produced a quantity of black smoke, and some carbon monoxide. Could any one say where and how perfect combustion was produced for industrial or commercial purposes? The speaker had been privileged in making experiments with a stove that did realize the ideal of no smoke, no carbon monoxide of perfect combustion, indeed the combustion was so perfect that it not only melted platinum but consumed the stove as well. Thus, a laboratory success proved a commercial failure, for no one would buy a stove which burnt itself up in a few weeks. The fact was that the problem still awaited a practical solution. They might reduce the volume of smoke, but they did not know how to abolish it altogether. But the advantages of perfect combustion were so enormous from the sanitary, economical, and æsthetic points of view, that every effort should be made to encourage research and inventions in this direction. The state and the municipalities should give some impulse and facilities to such endeavors."—*Lancet.*

The Rise of Surgery in Germany.—In Germany, even so recently as one hundred years ago, surgery was at a low ebb. George Fischer tells us that quacks of all kinds, "cutters" for stone and hernia, cataract operators, and bone setters flourished in the land. The public executioner, whose business it was to fracture bones and dislocate joints on the rack, was supposed thereby to have acquired a knowledge of disorders of these parts, and was consulted freely about them, so much so that Frederick the Great in 1744 published a decree limiting the power of these men, and while permitting them to treat fractures, wounds and ulcers, forbade them to practise medicine.

New Cure for Astigmatism.—An English popular weekly is responsible for the following gem: "In the public schools of some cities measures are taken, by presumably competent officials, to test the children's eyesight upon the assumption—often too well founded—that the parents are not sufficiently watchful in that important particular. A little boy came home one day, soon after the term had commenced, with the following note signed by the principal: 'Mr. Green: Dear Sir, It becomes my duty to inform you that your son shows decided indications of astigmatism, and his case is one that should be attended to without delay.' The father sent this answer the next day: 'Mr. Kershaw: Dear Sir, Whip it out of him. Yours truly, John Green.'"

SOME CLINICAL ASPECTS OF GOUT.[1]

BY BEVERLEY ROBINSON, M.D.,

NEW YORK.

To the practitioner of general medicine to-day, the most evident tendency is unquestionably the all-pervading disposition to localize human ills and to assign, if possible, a change of tissue to explain symptoms.

From the laboratory point of view and according to those who limit their researches in this direction, micro-organisms are brought to the front almost invariably, and serve to explain whatever morbid sequences may arise. When neither anatomical changes can be detected, nor microbes apparently causative are discovered, chemical research is appealed to, and thus theories, usually varied, are assigned to explain facts which are obscure.

The general pathology of former days saw undoubted facts also in atmospheric changes, constitutional peculiarities, habits of mind or body, which, because obscure and undetermined ultimately, are now relegated frequently to the past, and when appealed to merely seem for many to cloak ignorance or incompetency. And yet, how true it is for the man of large observation and philosophic mind to trace many of our ills to purely functional disturbances that probably shall never be clearly revealed, unless we should assume that the microscope, the chemical balance, and all other instruments of accurate research are given to solve the final changes of man's organism.

Such thoughts as these are forced upon one who sees, or believes he sees, many of the protean or obscure forms of gout, in apparently their mere functional expressions. In some of these cases there is history of a previous, well-marked gouty attack, typical perhaps in its localization and symptoms. After such an access more or less tissue changes remain; in rare instances, however, while the graphic history of an attack of gout is given by the patient, locally nothing perceptible remains to show where it had been present. Many examples there are, also, when we have practically very little to guide us accurately except our general medical acumen, or indeed the touchstone of treatment. Sometimes, of course, we feel we have a right to be suspicious of a certain pain or ache, because the previous history of ailments among ancestors, or with the father or mother of our patients, lends probability to our diagnosis. Particularly is this true whenever we are unable to find after careful inquiry any other sufficient causation in the case under investigation. We must, however, be willing to admit that until one or more anti-gout remedies have been freely and judiciously tried, certain cases appear absolutely obscure; and even with the use of lithia, the salicylates, and above all of colchicum, no satisfactory results may be obtained unless we meet squarely certain indications which are almost individual in their rarity or specificity. Thus it is, for example, that a single article of diet, or a particular drink, which one person may indulge in with relative or almost absolute impunity, to another seems to be the veriest poison and to bring out the gouty dycrasia in the most striking manner.

I confess to have a somewhat sceptical mind, the longer I practise medicine and the wider my observation has become, with respect of any absolute theory to govern dietary rules. It is true that with some patients a liberal meat diet will accentuate gouty tendencies, and to such a one vegetables and starchy foods appear singularly acceptable. If, perchance, one has just treated a patient of this sort, he is apt to be considerably influenced by the ideas of Haig, and to believe one very clear way of diminishing uric acid and its injurious effects is to limit the quantity of nitrogenized food to a very small measure. On the other hand, if we have just had the fortune to care for one to whom the starches and vegetarian diet are inimical and bring out morbid manifestations, we can then appreciate somewhat how a diet largely of meat, with a considerable limitation of starches and sugars, is above all essential. Again it seems evident, in certain cases, that it is mainly a question of what one man's stomach or liver is able to accomplish, and what another's can effect, and yet the explanation of this fact does not reside at present in any analysis we can possibly make of either urine or stomachal contents.

There is something over and beyond the mere chemical output, so to speak. To prove this, I would direct attention to what I have observed, and it is how the power of digestion for the same food will vary considerably under apparently similar conditions; how it will also change from time to time, without any adequate or sufficient cause, so far as we can judge. Again, we know, and I have seen it many times, that the very article of diet which theoretically would seem to be almost the worst possible for the patient is the very one that is easily assimilated and affords most satisfaction to the palate. Often, when a patient has expressed a longing for some particular food or drink, while at first I have had misgivings as to the wisdom of gratifying the intense desire, I have found by so doing that the patient has been much improved by my concession, and both enjoyed and digested the doubtful food thoroughly well. I do not wish to be understood as saying that this would be the invariable result, because I know the contrary to be true, and also I know there is always an element of risk in listening to and according to patients' vagaries or fancies.

There is a line to be drawn, a limit to be made, by the discretion and judgment of the wise physician, and it is to him that I have been and am now addressing my remarks. We are apt to forget, I believe, that in order to make food digestible we must render it palatable. We know very well that this rule holds good with a well person; assuredly it is even truer and more important about an ill person. Let the food or drink become distasteful in any degree, and I am quite sure, in many instances, it becomes equally difficult to assimilate it.

To what extent the central nervous system has power to produce this effect, I am not prepared to affirm,

[1] Read before the Practitioners' Society, October 12, 1900.

although I am convinced it is an important influence and has a decided action. I am also sure that, from a physiological standpoint, sapid substances, food served in an attractive form, tend to promote the secretion of the digestive fluids in larger amount. This is true invariably when there are mastication and deglutition. It is also true possibly when food is simply carried to the stomach by means of the stomach tube. It seems to me, therefore, that Ewald's test meal, consisting of a baker's roll and six to twelve ounces of weak tea without milk or sugar, is not a fair judgment of an already weakened stomach to bring out its real power, or to gauge the amount of free or combined acids, if we consider that most of us, even when perfectly well, would revolt not a little at such a repast being offered, except as a rigid and necessary experiment.

To what degree, we may ask, is suitable and well-considered preparation of food essential to proper combustion and reduction of its constituents to forms from a chemical point of view essential to our well-being, whether sick or well? The addition of a substance, such as sugar, in moderate amount, to many beverages and to some foods will not only render them more acceptable to taste, but will likewise help digestion, and in both these ways enable the digestive organs to transform them so as to be in no way injurious. It is here often merely a question of quantity. If the limit ordered by a certain personal equation be passed, sooner or later there proceeds either distinct palatal or stomachal revolt; and if these symptoms be not attended to, or over-indulgence be practised, and the individual be advanced in life, or has pronounced constitutional tendencies, inherited or acquired, we shall not infrequently be called to consider and treat manifestations which we must call gouty, for lack of some better or more satisfactory term. It is true, also, that we must be careful not to eliminate certain foods from our dietary regimen of people thus disposed, merely because generically they are in the same category as others.

There are assimilable starches easy of digestion to stomachs which rebel at others, and yet chemistry or even the microscope does not always tell us why. I have known many instances in which rice cooked in various forms was perfectly acceptable, when symptoms of dyspepsia would follow after a small portion of potato taken in any form. I have also known patients who could not digest at all a roasted or boiled potato, but could readily digest a potato that had been stewed or properly fried in thin sections. Of course, some changes may take place in the starchy granules by the mode of cooking, or through the ingredients combined with the potato, which render it perfectly suitable food even for an invalid stomach. We know this is true of bread: when fresh or not thoroughly cooked to extreme dryness, or cooked more than once, until we have either toast of the English or zwieback of the Germans, it occasionally retains the starch granules almost intact, or a large portion of the bread is not brought to that intermediate state of dextrin which allows the saliva to take hold of it and change it so as to become a most readily assimilable food.

In the matter of wine, malt liquors, and spirituous liquors, such as brandy or whiskey, habits in different countries certainly tend to put the mind of the judicious, careful practitioner in a very doubtful state. An Englishman, followed closely by the American of to-day, permits a small amount of good Scotch whiskey to many of his gouty patients, as being the least injurious form of alcoholic stimulant. The German considers that the light beer of Munich or Vienna will do no harm in moderate quantity, and yet he might place his veto absolutely on the stronger alcoholic stimulant, although ever so much diluted. The Frenchman will permit a small quantity of Bordeaux at dinner, while looking askance at brandy, whiskey, or beer.

Habits and climatic conditions no doubt are very important in determining the injurious or innocuous effects of all of these even in moderate quantity. I have the conviction also that racial peculiarity is no small factor in determining the bad or good effects of them.

I have known a German, night after night, and for many long years, drink one or several mugs of beer or ale, and be none the worse for it in any perceptible way. To the average American, such a habit would not be long in bringing about absolute functional disorder of stomach and liver, and finally be expressed in painful joints or neuralgic pains of no uncertain significance.

The moral of much that precedes is to show, as I believe it should, that no absolute theory of gouty troubles based on mere diet will answer many requirements of the clinician, and again that functional disturbances in various forms may arise when seemingly there is nothing to occasion them.

Many gouty expressions are simply made clear to us by one symptom, and that is pain. The pain may be localized and more or less continuous. It may be present only when pressure or movement is brought to bear upon the affected spot. I have noticed this particularly in two forms of gout, in which the pain was in the region of the sole of the foot or behind the heel. It has seemed to me that, in these and other instances, gout was separated from rheumatism by the fact that the heat of bed at night, or the fixed, more or less constrained position during sleep, aggravated rheumatic pains, while gouty pains were relieved or did not appear at such time in so marked a degree. This statement is not true of certain neuralgic pains, which are spasmodic in nature, come and disappear rapidly, and are simple twinges or severe shocks which make the most courageous cry out with agony. There are exceptions also to be found in those severe cramps of the muscles of the lower limbs which only a strong effort, or pressure, or bandaging of the affected member is sufficient to arrest.

In gouty troubles of the throat, and more especially of the larynx, all astringent or powerful applications are out of place. They almost invariably aggravate the local determination, and add to the patient's distress in a very evident manner. What is needed here must be soothing and anodyne. Why this is, is not usually appreciable by the senses. There may not be the slightest evidence of local inflammation, and yet the pain is acute and sometimes almost unbearable. In these cases I have known a spasm of the glottis of an alarming character to be brought on suddenly by the intemperate use of medicinal agents which ordinarily would cause little or no distress.

In some persons the gouty disturbance is apparently ushered in with functional upset of the liver. Under these circumstances, I have known the urinary excretion to present nothing abnormal, or, at all events, not enough so to be in any way characteristic of an impending gouty seizure.

Rapid dyspnœa has occasionally followed, of a distressing type, which nothing organic would explain, and relief was obtained only when colchicin was duly administered. I have little doubt, it is true, that many gouty manifestations which appear to be functional, or which still remain somewhat obscure, are of the nature of congestive or inflammatory disorders. I have seen this notably in the prostate, the uterus, and ovary, and rarely the intestine. My views in regard to the probable rheumatic or gouty origin of not a few cases of appendicitis are already known to many. In these instances, although it may be that a prior distinctive attack of acute, normal gout can be instanced, it is

not invariably true. Mainly for this reason doubtless, a few physicians and more surgeons are sceptical as to the existence of a gouty dyscrasia as efficiently causative of the affections to which I have referred.

We all know that the old-time physician believed in a peritonitis independent of our now over-worked appendicitis. These cases in my belief existed; they still exist. They do not require operation, and when operated on they show no lesion of the appendix and certainly none which justifies an abdominal section, or which would not end in thorough recovery with time and well-managed medical treatment. Of course, I do not wish to state that these cases are not very difficult to diagnose satisfactorily and in an accurate manner. Some of them give grave anxieties for a time, in adults and children, and both physician and surgeon watch for hours, or even days, thinking at any moment an abdominal section may be clearly indicated by reason of symptoms pointing unerringly to appendical inflammation, abscess, or perforation, which should admit of no further delay. Others there are which leave us in reasonable and just doubt, perhaps, for a while, and yet presently the pendulum swings toward operation because local pain, temperature, pulse, general condition, local resistance, all point to its need. When the abdomen is opened and the appendix explored, a slight or marked redness may be evident; there may be also some localized peritonitis, or the intestine itself in a limited area may be inflamed and shagreened on its outer surface. Some say remove the appendix, and proceed to do it, because they believe this organ is the *fons et origo* of the trouble; others are sceptical, and, after searching vainly in the abdomen for the evident cause of the trouble, sew up the abdominal walls and remain in doubt as to what the matter is.

To my mind the surgeon under like circumstances who abstains from doing more than this acts as wisely as may be. Nevertheless, the exploratory incision followed by searching for the obvious cause of the symptoms is a danger to the patient, although a less one than further operative interference, especially when what to do is not clearly indicated. It seems to me just as evident that the localized peritonitis was primary and causative, as it is to admit that the appendix began the sequence of morbid events.

The important question is, how an apparently unnecessary operation could be avoided, and this question is one which has now agitated the medical and surgical mind for many years. I wish fervently I could present it in an absolutely irrefutable manner. This I cannot do any more than I can point out invariably when gout or rheumatism has attacked another organ, as the tonsil, the ovary, or the uterus. What I can say still in all doubtful cases is: institute besides other rational treatment, local and general, a judicious anti-gout or anti-rheumatic guidance or treatment before operatory procedure is undertaken. I admit frankly that in some, not to say many, acute cases this appears almost impossible, or at all events it is obviously too hazardous. When an abscess has formed, when a sudden, fulminating case of appendicitis occurs accompanied with perforation, and if delay is permitted followed by grave peritonitis, more or less general, not to operate, and operate almost immediately, or indeed very soon, means death most probably, according to our present knowledge.

The other cases are the knotty or difficult ones, and here, as in many other instances of medical differential diagnosis, we are forced to make one by way of exclusion, and this oftentimes is as sure as the one made on a combination of signs and symptoms which may seem at first thought to be far more accurate.

As to cases of recurring appendicitis, especially in adults, those very numerous and increasing ones which are now operated upon in the interval, these I firmly believe, and I am more thoroughly convinced than ever of the wisdom of my position, should never be operated upon until a proper and preliminary anti-gout or anti-rheumatic treatment has been followed up, and for a sufficient length of time thoroughly to justify the operatory intervention if subsequently it must be resorted to.[1] Analogy with and experience about other organs convince me additionally of the proper conservatism of such a position. For example: I do not believe because a tonsil occasionally becomes inflamed and enlarged under rheumatic or gouty influences, it should therefore be removed, and I hold this belief for several reasons: first, there is a slight risk in the removal of a tonsil, particularly the adult one, on account of hemorrhage; second, even though removed, the inflammatory condition may and does recur at times in the stump; third, until the tonsil is practically proven to be an injurious or unnecessary organ as to its presence or physiological function, it should remain where it is; fourth, frequently it is but an index in its inflamed and enlarged state of the general condition of the organism; and if we are wise advisers we shall first endeavor rationally to change the condition of fluids and solids in the economy which occasions the local disease, rather than simply to remove the latter, and thereby conclude we have been of real service to the patient. What is true of the tonsil is true of the ovary, with added force in the latter case, because here the operatory procedure is more dangerous, and besides we are of the opinion that if one or both of these organs be removed, we have interfered with or annulled the power of child-bearing, and likewise effected future changes of qualities and disposition of the woman which occasion irremediable sorrow to the patient, and to one or more of those she loves best.

It is quite unworthy, in my judgment, in an argument of this kind for the surgeon to quote the relative innocuousness of an operation done to-day, according to the best technique, as justifying his action, no matter how little danger there is to the patient, unless it be proven that it is essential for the patient's best good.

We are apt, I believe, also to regard an operation too much from the point of view of mere danger and not enough from the standpoint of what shall be the ultimate result. How many times have I seen patients operated on, even by surgeons of widest experience and most careful, conscientious judgment, who have few or no thoughts subsequently except to wish that they had never had recourse to the knife. Sometimes the patients' bodily disability or suffering has been greater than if they had really borne the trouble they already had and had become accustomed to. Again, what is occasionally clearly defined is that, the local trouble being but the evidence of a general state, we cannot be sure, if we operate on one important organ or system, we shall not ere long have similar cogent reasons to operate on another.

A former patient of mine suffered torture for many years owing to trigeminal neuralgia, for which she submitted to much operative interference at the hands of dentist and general surgeon; subsequently, and although her neuralgic pains were by no means cured, she was forced to have a cholecystotomy performed to be rid of painful and threatening gall stones. Behind and beyond all this was unquestionably the obstinate old gouty condition that nothing, even the most rational medical, dietetic and climatic treatment, could neutralize.

This is admittedly an extreme and disheartening

[1] In children I would not insist upon an anti-gout treatment, other than proper diet and healthful surroundings, except in cases in which heredity was pronounced.

case. There are others and many of them, if not wholly similar, at least very analogous. For the sake of truth we must get beyond the individual case or the affected organ. We must recognize general laws that govern, and, for conscience as well as for the true advancement of our science and art, we should not throw aside or ignore the knowledge which has required centuries on the part of observant, accurate, skilful, laborious men to bring to light. Merely because our methods of research are fuller and more satisfactory to-day in many directions than ever before, is no reason why other and equally valuable knowledge, which is obtained by other means and from other sources, should not be duly estimated.

I have in mind, as I write, a patient who has been under my care for many years; she has had many functional disturbances; she has also suffered from many local determinations of constitutional gouty condition. A long while ago she suffered very much with an affection of the ears which the aurists claim to be a dry, proliferative catarrh often leading to chronic deafness, tinnitus, and other symptoms, and due mainly to impairment of movement of the ossicles and sinking in and thickening of the membrane. Local treatment by sprays, douches, pigments, politzerizing, introduction of Eustachian catheter, was continuously tried, but never resulted in more than temporary good; finally, the outlook appeared to be very considerable or absolute deafness, unless an operation might prove remediable. Knowing how unsatisfactory such operations are apt to be, I demurred. In the belief that anti-gout or anti-rheumatic treatment was indicated from the point of view of her general manifestations, it was adopted and persisted in, and finally after the lapse of several years her hearing is now about as good as ever, although the patient is no longer young, and all local treatment of the ear has been abandoned.

The cases of psoriasis, not to speak of other forms of cutaneous disorders, which occasionally fall into the hands of the general practitioner can be satisfactorily treated in many instances only when the underlying gouty or rheumatic dyscrasia is attended to. Sometimes this constitutional condition may affect particularly the intestinal tract, and then in addition to suitable dietary certain medicines must also be given to neutralize fermentative changes and to restore normal intestinal functions. Sometimes the constitutional tendency is toward the nervous system. This is below par, in an easily excited state. Hereditary influence is clearly present, and bad habits, such as a life in a poorly governed city often produces, tend to make it still worse in a rapid manner.

I know of several methods to correct this, but the surest and quickest is to get pure country air, if possible, live out of doors, go to bed early, have plenty of rest, and only diversions which prey least on the emotions. Without attention to these major indications, it seems relatively useless to pay regular visits to the dermatologist and cover one's self in part with lotions or salves. The so-called gouty dyscrasia is prone to affect the circulation, as is familiarly recognized.

How often do we see cardiac or vascular changes clearly of this provenience! In their minor forms, and particularly when the organic changes are only beginning, they are frequently difficult to recognize in a positive manner.

It is true that a slightly increased tension of the radial arteries, which is more or less continuous and accompanied with perhaps perceptible thickening of the vessels themselves, is indicative of blood changes already present. It is also true that an unusual quantity of light-colored urine of low specific gravity, with an occasional trace of albumin and a few granular casts will accentuate premonitions and confirm diagnosis. Still more certain are we when cardiac enlargement with slight hypertrophy is present and can be accurately made out by careful physical methods of research; but in those instances in which none of these is obvious, what shall we say many times? The heart action is often irregular, without apparently adequate cause; its beats may be feeble or too forcible, tumultuous; they may vary from time to time, rapidly or suddenly, and with these functional phenomena most unpleasant feelings may be present. Sometimes these annoying sensations are in the cardiac region and direct our attention there almost immediately. Again, the disturbance or pain may be far removed, and dizziness or persistent or recurring headache may be the sole warning note which may act as our guide and teacher. In these latter cases it is the physician who discovers the cardiac disturbance occasionally, and without the patient so much as directing his attention to it. Even then, if the pulse be interrogated, it will not invariably respond to our research by revealing to us any additional facts of value. It seems to be of good volume, force, and properly depressible. There are also patients who suffer cardiac distress, and who speak of localized pain, fluttering, gone sensations, intermission of heart beats, and when we put the ear to the chest we fail to recognize any symptoms of an abnormal character; in other words, the distress is purely subjective.

Every practitioner of even limited experience has seen at least some examples of the foregoing types. He may or may not attribute them to the true cause; he may regard the symptoms as purely fanciful or gross exaggerations, simply the outcome of a fatigued brain or hysterical disturbance; he may think that too much work, mental or bodily, malnutrition, or an excess of food, lies at the source of it all, and try by neutralizing errors or mistakes thus to effect curative results. Be that as it may, and while recognizing many instances in which success will reward effort in one direction or another, there are still some cases which remain very obscure, and in which failure to accomplish much that is real and beneficial is a sad commentary on the medicine of our day and generation.

Mere science in its narrow acceptation will not always accomplish it. We may weigh, and analyze, and delve with every scientific instrument and method at our command and in our service, and still we are forced back to the old-time method of theorizing and explaining as best we can.

It is the senior practitioner, the hospital clinician, the man whose opportunity extends also outside hospital wards, and who, wherever and whenever his methods are used to the utmost, also utilizes the very best men and talent that modern advances and enthusiastic, well-drilled younger spirits afford, who reaches nearest the truth.

In this thought there is much of consolation for the man who has grown somewhat old and tired in harness. He is no longer forced to submit and believe that every new aspirant for fame and honors has eliminated his worthy labors and efforts of a lifetime. His work and his doing are still good and will bear justly all comparisons with newer and other methods, more advanced at one point or another, but always to be subjected to, and under the control and supervision of, the more experienced, older, wiser head.

In Hip-Joint Disease the pain first complained of may be on the inner side of the thigh, or above the patella, or in the popliteal space, or about the knee, wherever the terminal branches of the obturator nerve are distributed.—*International Journal of Surgery.*

THE RELIEF OF PROSTATIC ENLARGEMENT.[1]

By JOSEPH B. BISSELL, M.D.,

VISITING SURGEON TO BELLEVUE HOSPITAL.

In the past few years so much improvement has been made in our treatment of prostatic enlargement and its results, that it seemed to me a short résumé of the subject, from a surgical standpoint, might be of interest to the members of the Practitioners' Club. A more intimate knowledge of the anatomy, physiology, and pathology of the prostate gland, and the changes following its enlargement, the wider use of the local anæsthetics, and the application of the cystoscope for diagnostic purposes, have, among other causes, helped us to a more exact appreciation of the value of the various curative procedures for the relief of this condition. No surgeon at the present time would open the bladder without first attempting to confirm his diagnosis by the use of the cystoscope.

To the minds of most of us, the middle lobe is the offender in about all of the cases of retention and cystitis following hypertrophied prostate. As a matter of fact, it has been shown that in the majority of cases it is not the middle lobe, or not the middle lobe alone, which causes this obstruction and its sequelæ. Of these causes of obstruction and changes in the tissue of the prostate, bladder, etc., I will speak later.

The interference with the function of the bladder by this obstruction produces cystitis, trabecular and sacculated walls—possibly calculi, renal disease, dilated ureters, infection of the whole urinary tract, and thus general sepsis. This may not occur in every case. The bladder muscle may be able to overcome the obstacle and empty the bladder completely or nearly so. For a time this compensation will continue, and in mild cases it may keep on to the end of life. If, however, the obstruction is too great, or the bladder muscle too weak to allow of emptying the bladder, a cystitis, with all its concomitants and results, soon follows and compels the patient to seek relief. For this purpose there are, in general, two ways for our consideration: Removal of the residual urine in an artificial manner, or removal of the obstruction, so that the bladder may again be able to expel its contents.

At the outset it is well to have it understood, by the patient as well as by the physician, that certain changes have taken place, secondary to the hypertrophied prostate, to such an extent in the walls of the bladder and urethra that it may be impossible to restore these to their normal function, even after the complete removal of the exciting cause.

For instance, a sacculated bladder, with its walls full of trabeculæ, such as I show you here, you would hardly expect to resume its duties, no matter how thoroughly the prostate had been removed.

First, as to the different ways for the artificial removal of urine: Systematic catheterization, or "catheter life," is the introduction of a catheter, withdrawal of urine, and the irrigation of the bladder by a proper solution for antiseptic and cleansing purposes, at regular intervals during each twenty-four hours.

Aspiration with a trocar and cannula above the pubes is a temporary means of relieving a distended bladder. This cannot be kept up long, although in one case, in which it was impossible to introduce a catheter, I aspirated three times daily, for over three weeks, without infection and with little pain or difficulty, and with the ultimate recovery of the patient.

When for some reason an operation on the prostate is contraindicated or catheterization is impossible, permanent drainage of urine through a fistula can be made.

Catheterization, if available, is always our choice for treatment of enlarged prostate and retention. It is practicable if, in a fairly normal bladder with a moderate amount of residual urine, it is possible to pass a catheter of fair calibre, at regular intervals, in a careful manner, with perfect asepsis, without pain or hemorrhage or infective reaction. Catheterization may answer well for years, the residual urine diminishing—or, at least, not increasing—until slowly or suddenly the symptoms become unbearably worse, or infection, as shown by a suppurative orchitis or cystitis, takes place; then some other means of relief must be found.

Vesical drainage for cystitis and enlarged prostate is a course we may have to resort to when there is inability to use the catheter, and when the local or general condition does not warrant a prolonged operation like a prostatectomy, or when the patient does not wish to assume the risk. This drainage can be made, by means of local anæsthesia, through the perineal route, or suprapubically, quickly and painlessly. By the use of a silver, rubber, glass, or other non-absorbable tube, a permanent artificial channel, leading to the bladder, may be kept open. Witzel makes a permanent fistula above the pubes by stitching the bladder wall over a tube for three-quarters of an inch and entering the viscus obliquely, like the operation for a gastric fistula. This, he claims, will not leak at any time and will be permanent. Through the perineal urethra a prostatomy may be made and a permanent fistula instituted by means of a catheter or glass tube sewed in or otherwise retained.

None of these methods are suitable for all cases. Catheterization may fail because of repeated attacks of infection. The patient may not have intelligence enough to use a catheter properly. He may not be able to afford the necessary accessories, or he may be too careless or indifferent. Certain patients, using every precaution that can be taught them, are constantly infecting themselves; just as others seem to have an almost immune genito-urinary tract and, in spite of want of cleanliness, never meet with an accident in the way of infection.

Sudden and complete retention of urine following enlarged prostate may call for immediate operative drainage, which may or may not have to be made permanent. Continuous drainage by means of a fistula is at best unsatisfactory and distressing. It is almost impossible to prevent leakage, in spite of the many devices that have been tried and are in use at present. The wearing of a rubber urinal is troublesome, humiliating, and depressing; and the constant and ready communication with air renders infection continually liable.

Various radical operations have been proposed and carried out. The oldest and most common is perineal prostatomy, which does considerable good temporarily, probably because of the drainage; but within a few months after the opening is closed and drainage, therefore, ceases, the symptoms frequently return. The other operations can be divided into two classes:

I. Those which aim to remove the obstruction by cutting off the blood and nerve supply, and thus produce atrophy of the gland.

II. Those which affect directly the obstruction itself.

First. The direct cutting off of the blood supply may be done by ligating the vessels supplying the gland.

The prostate is supplied by branches of the internal pudic, the median hemorrhoidal, and the inferior vesical. Anomalies are frequent, and the anastomosis is very free, so that, practically, as the vessels are numerous and deep-seated, it is best to tie off the main

[1] Read before the Practitioners' Club of Newark, N. J., October 1, 1900.

trunk. All these vessels arise from the internal iliac. This has been done by a Dr. Bier, of Kiel, who tied both internal iliacs. Dr. Willy Meyer, of New York, has also tied these arteries, with a result which he calls "encouraging in the extreme." The operation is not done often, in this country at least, and the difficulties and dangers surrounding it are too grave and the result obtained is too uncertain for us to advise the risk.

The blood supply to the prostate may be reduced indirectly by a double castration, theoretically.

The explanation is, "that we permanently remove the frequent intermittent active hyperæmia of the genital system, which is produced by the presence and secretion of the testicles by nervous reflex." I quote from Dr. J. William White. Owing to his enthusiastic advocacy, the operation was being performed quite frequently a few years ago. An analysis of the cases reported shows that in nearly every instance after a time all the symptoms returned. The mortality is much higher than one would expect to find it. It has been given as from seven per cent. to thirty per cent. by various reporters. The higher percentage must be due not to the operation, but to some fault in the surgical technique. Melancholia and mania are reported as not infrequent sequelæ of single and double orchidectomy. It seems to me that the theory on which the operation is based is as fallacious as the evidences of cure are incorrect.

Angioneurectomy of the cord, like so many other surgical procedures for this trouble, produces just as much atrophy of the prostate as rest in bed, irrigation, and other local treatment would produce, and no more. That these methods do bring about a distinct reduction in the congestion and œdema in and around the tissues of the prostate, there is no doubt; but that this is a functional and temporary relief for the most part, there is also no doubt. The observer who is looking for it will find a quite diminished tumor in this region, easily to be denominated atrophy, if he wishes to call it so, but probably due to the reduction of the engorged vesicular tissues.

Ligation, division, subcutaneous incision and evulsion of one or both vasa deferentia have all been proposed and tried by various operators, with practically the same results as above mentioned, as to the cure of the prostatic enlargement. The mortality in these operations on the vas is low, but the functional effect on the glandular enlargement is not of sufficient value to justify the risk of these operations. Mikulicz reported a number of cases of evulsion of the vas, in every one of which, at the end of a year, on the average, it was found that the old trouble had returned.

Second. The procedures which attack the gland directly. Injections of various irritating substances into the parenchyma have been tried without success and may indeed be dangerous. Electrolysis has been proposed, but never successfully tried.

Destruction or removal of the obstacle at the internal orifice, by means of an instrument carried into the bladder through the natural channel, the urethra, seems at first thought to be an ideal way. The instrument of Bottini fulfils the indications above mentioned. The operation is in effect a multiple galvano-caustic division of the middle lobe of the prostate. The instrument has been modified in several details since the Italian surgeon first presented it in October, 1875. As then made, it looked not unlike a medium-sized rubber catheter with a short beak. On this a porcelain disc carried a platinum plate, which was heated by an electric current. By means of this an eschar was made on the prostatic projection in the bladder at varying points. These eschars came away, leaving a cicatrix, which, contracting, produced an atrophy of this part of the prostate.

Bottini reported five successful cases in two years with this instrument. Later he modified it, so that at present it resembles a lithotrite, in having a male and female blade. In the former is a platinum knife, which leaves and returns to the groove of the female blade by the turning of a screw, and is connected to an electric current. A scale at the outer extremity shows the depth of groove cut. A cooling apparatus surrounds the instrument, so that it is kept free from heat while the knife is raised to a white heat. Freudenberg modified the instrument by making the blade of iridium alloy, rendering it firmer and less difficult to heat, and also in various other ways changed it greatly to its advantage.

Dr. Willy Meyer, to whose writings on this procedure I am indebted, has carried out almost to perfection the methods and manner of using this instrument. He prefers the street current with a rheostat, but a fifty-ampere storage battery can be taken to the patient's house, if necessary. Dr. Meyer's personal cases, twenty-four in number, show eight per cent. mortality directly due to the operation, and eight per cent. mortality indirectly due to the operation, with thirty-eight per cent. of cures.

The Bottini operation is not so simple or so easy as at first sight one would expect. It is an operation of detail, and one which requires care and skill and an intimate and clear knowledge of the exact condition of affairs in the bladder neck. It is an operation by no means devoid of danger. Death, following suppression of urine immediately succeeding this procedure, has occurred several times, to my personal knowledge. Freudenberg reports a case in which he cut through a fold at the base of the bladder; sepsis and death resulted. Perforation of the urethra and sepsis are reported. Pulmonary emboli have been found at autopsy. Hemorrhage is a constant danger, and the greater in that it comes on at the time the sloughs are thrown off—about ten days after the incision. It may take place earlier. Cystotomy and tamponing have been necessary in a number of cases, in order to save the patient's life. Absolute retention is not an infrequent immediate result of the operation. In one of Meyer's cases he was obliged for this cause to tap the bladder over the pubes for three days. Pain and severe tenesmus, almost unbearable, are not infrequent complications. Dribbling is an occasional sequel which may be permanent. But the most serious of all the objections to Bottini's method is the risk of sepsis. In every case of enlarged prostate which comes to us for treatment there is already a cystitis, or all the elements preparatory to its development. There are present a number of pathological changes in the mucous and other coats of the bladder, as well as the tissues of the prostate gland and its adnexa. A trauma, such as is done by the Bottini instrument, is all that is needed to light up an inflammation in these tissues. The destruction of a considerable amount of tissue in a closed sac, and the leaving it there without drainage, seems to me to be a surgical negligence without any excuse. To say that it is done with every antiseptic precaution is saying what is impossible. The cicatrization produced by a Bottini is said to prevent or complicate seriously any further radical operation upon the gland. Moreover, this procedure does not take into account the real causes of the obstruction and its sequences, or at least affects only a small proportion of them. If the retention, cystitis, and their results were caused by a bar or a collar or other obstruction at the lower portion of the vesical opening only, the Bottini would, apparently, be the indicated operation, always provided free drainage afterward could be instituted to prevent septic infection. A catheter tied into the urethra, to my mind, is a brutal and painful relic of the dark ages of genito-urinary surgery.

Bottini's operation does not adequately appreciate the causes of the obstruction. It does not treat the condition complicating the hypertrophy. It does not allow for drainage of a dirty wound. In a word it is unscientific and unsurgical.

Prostatectomy is the removal of all or most of the prostate gland. In order to consider its merits properly, it is necessary to understand clearly the pathological anatomy and physiology of the condition we have to deal with. Obstruction to the complete emptying of the bladder and the results of this obstruction —cystitis, repeated attacks of retention, trabeculæ, and sacculated bladder, calculi, inflammation of the ureters, pyelonephritis, and sequelæ—are due, as a rule, to more than one factor. Our knowledge of the anatomy and relations of the pathological prostate has been greatly advanced by the recent investigations of the subject by Dr. Samuel Alexander, of New York. The careful and elaborate researches and dissections made by him at different stages of the condition known as hypertrophy of the prostate, show a considerably more complicated cause of these results than the one usually given of enlargement of the middle lobe.

The prostate gland consists of two lateral lobes joined by a middle isthmus. Backward and upward from this projects the middle lobe into the floor of the bladder when enlarged, the apex being at the opposite end toward the membranous urethra. Dissections of a number of pathological prostates show three general varieties of enlarged prostate and resultant obstruction.

First. Enlargement of the middle isthmus, forming a bar at the internal meatus, with enlargement of the middle lobes.

The second form consists of a growth of the middle isthmus, with enlargement of the glands which lie beneath the mucous membrane at the vesical orifice.

A third form is made up of the growth and development of the prostatic glands above the verumontanum and an intra-urethral growth. Of course, the variations from these types are great and frequent. The middle-lobe variety may at times be pedunculated, it may be crescentic in form, or nipple-formed in shape and size both, or in shape of a collar surrounding the vesical orifice. The distortion of the prostate also brings about a want of proper relation in the insertion of the vesical and urethral muscles arising in that neighborhood. As a result, the vesical outlet closes irregularly and before the bladder is emptied.

Another cause of retention is venous stasis, the resulting œdema therefrom further increasing the obstruction. The constant straining of the muscular walls of the bladder to overcome its disability produces finally overstretching of the vesical muscles, changes in the walls from prolonged inflammation, and connective-tissue atrophy, from which the resulting trabeculæ and sacculæ increase the difficulty of a cure.

The hypertrophy may consist, structurally, of glandular tissue mostly, or with the fibrous tissue most prominent, this being usually simply a later stage in the enlargement. Often an acute congestion of the gland and its surrounding structures may account for complete obstruction and retention.

In considering the best radical treatment, all these conditions and distortions of the gland, of the muscles, of the bladder, of the deep urethra, and the mucous membrane, together with the causes and the anatomical relations of the pathological state called hypertrophied prostate, as well as the patient's constitutional condition, have to be taken into account. Not at all a simple problem, and, in a certain number of cases, if complete cure is expected, a distinctly unsolvable one.

No operation or ameliorating procedure will do more than give a certain amount of relief to a patient with an old pus bag of a bladder, with complete atony of the muscular coat, and with deep sacculations in which decomposing urine and phosphatic deposits are continually occurring. Furthermore, the danger to life in some of these old men from even a simple emptying and washing out of such a bladder is known to us all, by that most convincing of teachers—experience.

Theoretically, the indications for treatment are two: removal of the cause, and removal of the results. Destruction or removal of the offending obstruction does not remove the diseased bladder or restore the dislocated muscular insertions, or renew the disorganized and degenerated bladder wall; but complete removal of the obstruction if possible, and then drainage and constant irrigation of the bladder and the pockets and sinuses connected with it, will help a great deal toward bettering the conditions which it has taken years to produce. Prostatectomy and drainage with frequent irrigation is the nearest approach to a fulfilment of these indications. Drainage alone can be accomplished by means of a prostatotomy, but this does not remove or make any attempt to remove the cause of the trouble.

There are three ways by which prostatectomy may be performed: by the suprapubic route, by operation below the pubes, and by a combination of both these methods. The suprapubic route is open to serious objections. First, and of perhaps most importance, drainage is up hill and against the force of gravity. Shock is much greater than in the perineal operation. The floor of the bladder is extensively lacerated. The prevesical areolar tissue is easily infected, and sepsis is not an infrequent result of opening a purulent bladder above the pubes.

There is no advantage in the combined operation that is not present in the infrapubic one, while the time of operation in the former is nearly doubled. Shock is consequently much more severe and hemorrhage is more likely, with the chances of infection increased by the added manipulation required by a double operation.

Posterior prostatectomy, by a sacral route, is a long and tedious operation, with no special advantage.

Perineal prostatectomy has many attractions. By it the prostate is easily reached. Hemorrhage is light or is easily controlled. Drainage is in the shortest and most direct route by force of gravity. The opening into the bladder is at its most dependent portion, and the best possible irrigation is obtained for both bladder and urethra. Sepsis following this formidable operation is, therefore, less apt to occur. The urethra need not be injured nor the floor of the bladder, except at the point where drainage is to be made. With the perineal prostatectomy and drainage, restoration of function, with minimum danger to life, can be expected in suitable cases and when the operation is done by experienced surgical hands with exact knowledge of the anatomy of the region and the structures involved.

The perineal operation is quite simple. The patient has been prepared by several days or more of rest in bed, irrigations of the bladder, and gr. viiss. of urotropin night and morning. Cystoscopy is used at least once, to give the operator a good idea of the inner surface of the bladder and the amount and shape of the hypertrophy of the middle lobe. The patient is given calomel the night before, with a saline purge in the morning preceding the operation, and the rectum cleared out with thorough irrigation. The bladder is also irrigated with Thiersch's solution just previous to beginning, and four to six ounces of this solution left in. A full-sized sound is passed to the bladder and held in by an assistant.

I prefer the lateral to the median incision, as it gives more room. It is made slightly crescentic with the convexity upward, its centre being a little less than half-way from the anus to the perineo-scrotal junction. The patient is in the lithotomy position. The incision is two and one-half to three inches or more in length. The left forefinger in the rectum locates the prostate and also warns the operator when he is approaching too closely to the rectum. The incision is carried by careful dissection down through the tissues to the membranous urethra, where the sound locates that canal and the apex of the prostate. Stripping the tissues from the apex backward can be very easily and rapidly done, either by means of a blunt dissector or with the right forefinger nail. The left forefinger in the rectum assists in forcing down the prostate and acts as a guide. Without care considerable laceration of the rectum can very easily happen.

At this stage of the operation a volsellum hooked into the apex draws the prostate very satisfactorily into sight. The capsule, stripped pretty clean inferiorly and anteriorly, can then be incised on either side of the urethra and each lateral lobe pulled out as a whole, bringing the middle lobe with them. If the enlargement is a fibrous one, this is surprisingly easy after one has done it a few times; if, however, the hypertrophy is mixed or the glandular element predominates, the enucleation is much more difficult. The mucous membrane of the urethra and bladder is quite likely to be lacerated, unless extreme care is taken.

In some cases these manipulations can be greatly aided by incising the urethra in the posterior membranous portion, withdrawing the sound, carrying the right forefinger through this opening into the bladder, and pressing downward the middle lobe, thus assisting its enucleation. An Edebohls speculum in the wound allows of better access to the inferior and posterior surface of the capsule. Great care is needed to separate the prostate from the floor of the bladder without injuring the latter. The secret of success is to keep within the capsule. It is better to leave behind small portions of the prostate tissue than to risk lacerating the bladder wall by a too close dissection. If the middle lobe is a pedunculated or teat-like process this accident is almost impossible to avoid. Even if it occurs it is not necessarily dangerous. It is better to connect this opening, if made, with the urethral wound.

Hemorrhage usually ceases when the prostate is removed; if not, hot irrigation and a few moments' pressure with hot gauze or sponges will control it. A large, firm drainage tube is fastened in the wound, so that it opens just within the bladder, and the lower end of it attached to a continuous drainage apparatus. A strip of acetanilid gauze is placed loosely in the wound to drain the cut surfaces.

At the end of the third or fourth day, and every fourth day thereafter, a full-sized sound is passed down the urethra to the tube, and after its removal to the bladder. This tube is used for irrigations twice daily. As the irrigation of the bladder is a most important detail if we wish to cure the chronic cystitis, the tube is left longer than would be necessary for simple removal of the prostate gland, the time varying according to the condition of the bladder wall. After it is taken away the viscus is washed out by a catheter passed through the wound.

The average time before the wound is closed is six to ten weeks, but long before that the patients are able voluntarily to expel their urine, the bladder retaining it in the interval without loss. In two cases in which I operated, in April last, in the above-described manner, both were up and out of doors, with the wound closed, one in June, the other early in July. One of these patients was fifty-nine, the other sixty-four years of age. Both had atony of the bladder, both had several ounces of residual urine. The amount in one case was fifteen ounces. In neither case is there at present any residual urine. The urethra is one-half to one inch shorter in each case. There is no dribbling. The intervals are six hours at night and four to five hours during the daytime.

The results of a perineal prostatectomy become more favorable as improvements take place in the surgical technique, in the methods, and in the time employed in the operation. Statistics prove little, nothing, or everything, as a rule, to suit the theory of the writer of any special subject. Some time ago Dr. Watson, of Boston, reported a series of nine cases with no fatal result. Then his next patient died, giving a mortality of ten per cent. At a certain hospital in New York I found a mortality of sixty-six and two-thirds per cent., but a close examination of the hospital records showed that three patients had been operated on, of which two died. Of two books published about the same date, one gives a percentage of mortality of twenty-five to twenty-eight per cent., the other of twelve to fifteen per cent.; so much for the fallacy of statistics.

Of the dangers of the operation, hemorrhage is one of the least and can be almost always avoided by reducing, as completely as possible, the congestion and œdema before operating. Injury to or rupture in the rectum is likely to occur only if the operation is done too hurriedly, or if there be adhesions present, or in very large prostates. The rent should be at once repaired from the perineal side, the sutures being kept from appearing in the rectum.

Sepsis is, of course, an always present danger, but never more so than in any other operation under similar conditions. When free drainage can be obtained, this can be minimized by attention to surgical technique and to the preliminary preparations. The danger of the anæsthetic is ever present. The safest is nitrous oxide gas and ether. Hypostatic pneumonia is a source of danger. Uræmia has been responsible for the greatest number of deaths following the operation, but it is not peculiar to this special procedure.

Dribbling and incontinence, due to rupture and laceration of the sphincter vesicæ at the time of operation, may occur; but, with care in the digital dissection, it may be prevented.

Shock depends upon the loss of blood and the length of time of the operation, and it is to be treated by avoidance of these two causes as much as possible, and by intravenous saline injections toward the end of the operation and after it, or earlier if necessary.

To recapitulate, dissections of the pathological prostate show that hypertrophy is almost never confined to the middle lobe alone, but that the whole of the prostate is involved. This involvement is glandular and fibroid in character. The older the case, the greater the predominance of the fibroid element. At times there is a venous congestion and a stasis also of the capillaries, which adds a vascular element to the size of the prostate and its adjacent tissues. Any operation which does not attack the hypertrophy of the lateral lobes is not radical and cannot effect a permanent cure. The removal or destruction of the middle lobe, in the great majority of cases, only partially if at all removes the cause of the obstruction, although the multiple cauterizations may so relieve the capillary stasis and œdema of this portion as to give a very decided temporary relief; and if most of the obstruction in any special case is due to this condition the relief may be marked and last for quite some time, provided the bladder and kidneys have little or no secondary disease, and provided sepsis does not follow.

From the above we may assume that perineal pros-

tatectomy with drainage is an operation—in competent hands—which is no more dangerous to life than an interval operation for appendicitis, provided the cases are properly selected ones, in which degeneration of the general and special tissues of the body has not gone on to a hopeless extent, in which the bladder and kidneys are not too seriously damaged, and in which septic infection, if present, is not too profound. But, even under part or all of these adverse conditions, complete removal of the prostate with free drainage is the rational and scientific method of radical treatment, and offers the best hope of relief, and the most favorable chance for a permanent cure, with the least danger to life.

15 West Fifty-eighth Street.

THE CONSTANT QUANTITY IN THE VARIOUS CLIMATIC TREATMENTS OF TUBERCULOSIS.

By C. G. CAMPBELL, M.D.,

PHŒNIX, ARIZ.,

LATE PHYSICIAN TO NEW YORK CITY HOSPITAL; FELLOW OF THE NEW YORK STATE MEDICAL ASSOCIATION.

It should not be necessary to defend the climatic treatment of tuberculosis. Unfortunately from high quarters in Germany the declaration has of late gone forth that climatic treatment is of no value, and with some of us anything emanating from Germany is considered *ex cathedra*. Let it be remembered that a few years ago practically the only sufferers from phthisis that received any benefit were those who resorted to a suitable climate. Many of these entirely regained their health. If better methods of treatment have improved our results under ordinary conditions, it is only rational to hold that these better methods will be still more efficacious in a climate which is highly beneficial of itself. This is a most important question. If climate is of benefit the physician is making a serious error in not giving his patient the advantage of it.

The writer is of the opinion that the principal point possessed in common by climatic conditions beneficial to phthisis is the discouragement of germ-life and thereby the prevention of reinfection. The following conditions found in various climates may be enumerated as discouraging to germ-life:

(*a*) High percentage and volume of sunlight.

(*b*) Temperature of sun sufficiently high to promote sterilization.

(*c*) Dryness of atmosphere.

(*d*) Porousness of soil.

(*e*) Constant freezing temperature.

(*f*) Infrequency of habitation.

(*g*) Unfavorable conditions for the formation of dust.

The first three conditions are actually germicidal and positive in their action. The last four simply offer a poor soil for germ-life and therefore are not so valuable. Taking the discouragement of germ-life as our thesis, we will find that climates possessing apparently opposing qualities have this common point though produced by different conditions. For example, the high altitudes of Colorado with a rarefied dry amosphere, small rainfall, and high percentage of sunlight present exactly opposite conditions to those obtained on the open sea. And yet a long sea voyage is as beneficial to many cases of tuberculosis as is a high altitude. The explanation is easily found in that the volume of sunlight and dryness of atmosphere in the high altitude discourage germ-life, whereas the entire absence of dust to carry germs and the absence of population to produce them free the patient from the danger of outside infection on the open sea. Without a detailed analysis it will be found that every climate beneficial to tuberculosis discourages germ-life through some of its qualities. The high percentage and volume of sunlight and the dryness of the atmosphere are undoubtedly the qualities of greatest importance. The greater extent to which these are possessed by a climate the greater is its curative value. Ozone was formerly dwelt upon as the element which gave climate its value. There is no question that ozone is germicidal, but there is no accurate method of measuring the percentage of ozone in the atmosphere and therefore the benefit that a greater or less percentage produces. Whatever its exact value its action is common with that of the before-mentioned conditions, namely, the discouragement of germ-life.

A high altitude has been held to be of benefit. There is a question if this belief is not founded on a false theory, and it is possible that patients improve in a high altitude because of the sunlight and dry atmosphere and in spite of the altitude rather than because of it. In many patients the heart action is greatly overtaxed by a high altitude. It certainly increases the tendency to hemorrhage, and a patient who recovers in a high altitude usually finds it necessary to remain there the rest of his life. However, whether a high altitude possesses positively detrimental qualities or whether the criticisms of it are merely academic, there is no doubt that innumerable cases have been greatly benefited under the conditions there prevailing.

The writer having had considerable experience in the treatment of tuberculosis in the climate of the low altitudes of Arizona, feels warranted in stating his observations of its value more to uphold climatic treatment in general than to advocate this climate in particular. In configuration Arizona slopes from an altitude of seven thousand feet in the northeast to practically sea level in the southwest. The territory is protected on all sides by mountain ranges ten thousand feet high, and is not subject to the continental waves of temperature change. The low altitudes are exemplified in the extensive valleys of the Gila and Salt rivers. This combination of low altitude and excessive aridity is not found elsewhere on this continent. Here the altitude is under fifteen hundred feet. The low altitude not only serves to make the temperature mild, but the configuration of the country and the peculiar influence of the Gulf of California make it one of the mildest climates in winter, as well as one of the hottest in summer. In the months of June, July August, and September the heat is intense, though comparatively easy to bear on account of the very low humidity. Many sufferers from phthisis make great improvement in these months; there are others who do not stand it well, and these can best spend the summer months farther north or in higher altitudes where it is cooler. From October 1st to June 1st no more favorable conditions for phthisical patients can be found. In December and January the nights are a little cool, but in the daytime the temperature in the shade at midday is seldom under 60°, and in the sun it is 40° to 60° higher. There is practically not a day in the winter that a patient cannot sit in the open air for six hours or more with perfect comfort and pleasure. Patients who have gained during the winter months make especially rapid improvement during the spring months. The percentage of sunshine is not only very high, but, what is especially beneficial, its volume is very great. This is not only evident to the eye, but is well shown in photographic work, where the length of exposure to light required is less than half of that under ordinary conditions. The sun furthermore throughout the greater part of the year exerts a sterilizing effect by its heat. In the winter months the heat of the sun is over 120° almost daily, and in the summer a thermometer placed in dust in the sunlight will register from 170° to 200°.

There is less wind than in any other part of the United States. This is a most desirable condition to a patient who has very little subcutanous fat.

The most distinctive feature of this country, and the one in which it exceeds all others, is its aridity. It is a desert not because the soil is unfertile, but because very little rain falls, and that which does is almost immediately evaporated by the strong sunlight. There is so little moisture in the air that dew is unknown. The annual mean relative humidity of Phœnix is 36 per cent., the lowest recorded in the United States. That of New York is 75 per cent. Relative humidity as low as 3 per cent. has been observed, and an afternoon record of 5 or 6 per cent. is common. The lowest relative humidity recorded in New York in 1899 was 40 per cent. It will thus be seen that the dryest single observation in New York is not so dry as the annual average in Arizona. It is proper to note just here that where there is great dryness of the atmosphere the change of temperature between day and night is very rapid. This is necessarily so because there is very little moisture in the air to retain the heat of the sun. This is of no consequence to the patient in the morning when the atmosphere is getting warmer, but in the winter months when, in the afternoon, as the sun's rays become less vertical, the atmosphere gets rapidly cooler, it is very easy to catch a cold. This is due not only to the quickly falling temperature but to the rapid evaporation from the skin occasioned by the dryness of the atmosphere. Patients are especially vulnerable just after taking exercise. This mishap can be easily guarded against if patients are properly advised and follow instructions.

It is an important question which patients to send to this climate, and which not to send. Of the ordinary cases of subacute or fibro-caseous phthisis, practically all improve who have not reached the cavernous stage. In patients with small cavities the disease is often arrested, but their complete recovery takes a very much longer time. When there are large cavities, and especially when there is bronchiectasis, the patients do not seem to do as well as in a mild maritime climate. In fact the very dry air and the diurnal temperature range seem to aggravate unduly the sensitive bronchial mucous membrane of these patients. Cases of acute or galloping phthisis as manifested by a high remittent temperature do not do well anywhere unless they become transformed into the subacute variety. It is reasonable to believe that a favorable climate will increase the possibility of this transformation in such cases. The physician is warranted in advising them to seek climatic benefit, provided they or their friends clearly understand the exact situation. Climate seems to be altogether hopeless for cases of acute general tuberculosis. The wise physician, in sending a patient to a beneficial climate, will not give him definite assurances as to when he can leave it with safety. To tell a patient that he will be well after six months there, however slight and incipient his disease, is a very indiscreet procedure. While patients often look and apparently feel well after six months in a favorable climate, the chest seldom shows complete arrest of the process, and relapses on returning to their former homes are only too common. A prudent rule for a patient to follow is to live in a favorable climate until a year after his cough and expectoration have entirely ceased. In sending a patient away it is best to advise him that he will probably have to devote several years to the sole object of regaining his health, and that he will have to sacrifice every other consideration.

It is well, before sending a patient away, to make an attempt to improve his general nutrition to an extent that he may be strong enough to stand the journey. It is highly desirable that he should have a companion competent to save him from all care and extra exertion while on his journey, as well as to assist him to get settled when he reaches his destination. In many cases favorable under ordinary circumstances the patients suffer a drain on their strength too great to enable them to react, owing to their having to provide for their own necessities during a long journey.

The management and treatment of a case of tuberculosis are just the same in a beneficial climate as in one that is not so beneficial. The natural conditions being more favorable, a larger percentage improve, and the improvement is much more rapid. Speaking generally, the two main objects to be kept in view in the treatment of tuberculosis are the prevention of reinfection and the increase of resistance. The prevention of reinfection, while generally recognized, is not given the supreme position of importance which it should hold in order to secure the best results in the treatment of tuberculosis. There is no doubt of the fact that even when the patient's sputum is carefully sterilized there is often reinfection from dust particles in the atmosphere, which in a populous community is always more or less infected. It is in this respect that the favorable climate gives the patient an advantage and the physician an adjunct in treatment that cannot possibly be gained in any other way. This tendency to the prevention of reinfection is the constant quantity possessed by all favorable climates to a greater or less degree, and until it is possible to exterminate the tubercle bacillus in the air or in the human organism, climate will always favorably influence treatment and afford the patient a better opportunity for recovery.

While emphasizing the importance of the prevention of reinfection gained by climate, the increase of resistance by the now generally accepted measures of open-air living and superfeeding is regarded by the writer as of equal importance, and these measures should be practised as faithfully and in as great detail in a favorable climate as in one not specially favorable. It is not within the scope of this article to go into the details of these methods, but their efficiency is very great if practised thoroughly and for a long period. Otherwise the results are apt to be disappointing. Furthermore it must take a long period of time and the combined judgment of many observers to establish the exact value and limitations of these methods. It is usually the case that more is expected of new remedies than their completed test realizes. It seems highly probable to the writer that it will be found, in addition, that these methods must be practised for a much longer period after the disease has become arrested than is now deemed necessary. Six months of mercury was originally regarded as sufficient permanently to arrest syphilis, but three or four years is now regarded as a conservative period. While the analogy is not a close one, it is sufficient to illustrate the point. Sir James Paget said that no disease ever gets entirely well. This is in a sense true, but many diseases get well enough for all practical purposes. In phthisis which has been arrested there is a permanent impairment of the respiratory function and an established susceptibility to the tubercle bacillus. A case which has been arrested or which has been pronounced cured should therefore always be regarded much in the same light as a case of renal disease which is quiescent or one of valvular disease in which compensation is maintained. It is much better for the patient's welfare for him to regard his disease as arrested rather than cured. In a case the course of which is favorable there are, clinically speaking, three stages in the progress: the first, in which there are active signs of disease and the nutrition has not reached par; the second, in which nutrition is good and weight approximately normal, but in which there are still cough and expectoration and signs in the chest that cicatrization is not complete; the

third, in which nutrition is good, cough and expectoration have disappeared, and in which there remains only a little dulness and harsh respiration in the chest. The patient is usually amenable to discipline in the first stage. The second is the most dangerous stage, for, exultant in his improved condition and renewed hope, he is only too apt to abuse himself. He cannot be made to realize that each successive recrudescence of the disease is the more and more difficult to react from, and so he progressively detracts from his chances of permanent arrest. Even in the third stage he should be more or less under the surveillance of the physician, and should promptly consult him upon the slightest deviation from complete health. Strict obedience should be the motto of the patient, and infinite care that of the physician. Therefore while it seems certain that a favorable climate gives an advantage not otherwise obtainable, in order to afford the patient his best chance he should have not only such a climate, but in addition the most careful medical supervision. Some patients will get well by modern methods of treatment without climate, others by climate without treatment, but modern methods of treatment and climate together will save many patients who would otherwise succumb.

CHRONIC COPPER POISONING AMONG ARTISANS.

By HENRY A. KURTH, A.M., M.D.,

SCHENECTADY, N. Y.

Introduction.—If an artisan at his regular occupation takes into his system some of the material in which or with which he works, and this acts injuriously to him, we have a case of so-called occupation poisoning. The varieties of occupation poisonings are numerous, but most, because of their rarity, receive little attention. Chief of these poisonings to-day is lead poisoning. This from its frequency is nearly always recognized and rationally treated. Copper poisoning, on the other hand, is at present only too rarely diagnosed, and its treatment is anything but rational. Until within the last twenty or thirty years copper poisoning was not at all common. But with the enormous growth of manufactures in the United States these cases have become so numerous that any physician in a manufacturing city is likely to meet them. The object of this paper is, therefore, to impress on the city practitioner the growing importance of this subject. Cases of this kind are abundant here at the Edison General Electric Works, and it is from among these that the material for this article has been largely drawn.

Etiology.—Among what kind of workmen, then, are we to look for copper poisoning? In a general way, any man working in copper, or more commonly its alloy brass, is sure to get some of it into his system. In fact, some persons need only work in the same room where the metal is used to get enough of the poison to cause symptoms. This may seem exaggerated, but I have repeatedly found it true, and the reason for this will be seen later. It was among brass founders that the disease first received attention. To-day brass founders form but a small percentage of brass workers. Fully as numerous are the solderers. These men are very quickly affected. Other brass workers, such as filers, turners, stampers, grinders, and platers, are all more or less slowly affected. The most dangerous employment, however, is that of the finishers or polishers. Many of these use the buffing wheel, which fills the air with fine particles of copper dust, directed toward the workman. The copper enters the system by both the alimentary and respiratory tracts. A small quantity is taken in daily with the food and occasionally with water that has been exposed to the dust of the room. Most of the copper that enters the system first passes through the nose. From the nose it takes two courses. Some of it passes straight through the nose and throat into the lungs, whence by means of the lymphatics it is carried into the general circulation. The larger portion, however, is caught up by the mucus of the nose and throat and then swallowed. In the blood and the tissues the copper is probably stored up in the form of an albuminate. The length of time it remains in the system is still a matter of speculation. I believe it to be a question of months, with elimination constantly going on. Copper is eliminated from the system by the liver, the kidneys, salivary and intestinal glands, and to a slight extent by the skin.

Pathology.—In order to understand the pathology and the symptoms it is necessary to recall the physiological action of copper. Locally copper is both an astringent and an irritant. Constitutionally it is an agent promoting waste. Its astringent and irritant actions come into play at its entrance into as well as at its expulsion from the body. Its action promoting waste comes into play during its passage through the tissues of the body.

In the respiratory tract the irritant action seems to predominate. The nose, pharynx, larynx, trachea, and bronchi are intensely congested. The parenchyma of the lungs is probably at first also congested. Sooner or later, however, there is destruction of the epithelium of the bronchioles and air vesicles with the formation of new connective tissue. The lungs being thus far crippled offer an excellent field for pathogenic germs, notably streptococci and tubercle bacilli. Consequently most of these cases end in purulent bronchitis, or phthisis, or both. The part of the lungs not consolidated then takes on compensatory emphysema. The stomach being the chief port of entry of the copper suffers proportionately. At first there is a simple chronic gastritis. Sooner or later this invariably ends in chronic atrophy of the mucous membrane. Cases of such complete loss of digestive power as one finds among old copper workers one rarely meets elsewhere. In the intestines we find no constant lesion. This seems to be due to the fact that the activity of the copper is largely used up in the stomach. The liver is the principal storage-place for the copper. Its normal functions are generally somewhat interfered with. Gross lesions (cirrhosis) are rare. The spleen is enlarged in most cases, but is in no way characteristic of the disease. The blood, important as it is, has not been studied sufficiently to warrant any statement, except that the copper combines with the hæmoglobin of the red blood corpuscles and so diminishes their usefulness. The arthritic diathesis one frequently finds among lead workers is not found among copper workers. For this reason any attempt to explain copper poisoning as analogous to lead poisoning will fail. It will be remembered that a large portion of the copper is eliminated by the kidneys. We would naturally expect these organs sooner or later to become the seat of a chronic inflammation, especially interstitial nephritis. This, however, is not common, and the kidneys give but little trouble. This is another instance in which lead and copper do not act alike. On the nerves copper acts as an irritant, and this action is responsible for a great many symptoms. Some authors claim that copper causes various forms of neuritis, paraplegia, paralysis agitans, and even locomotor ataxia, but they have failed to exclude alcoholism and irregular living as causative factors.

Symptoms.—The skin is sometimes the seat of eczema. This is found on the face, back, or wherever there is persistent local perspiration, and is marked by the obstinacy with which it resists treatment while

the patient remains at his work, but heals readily with change of occupation. The hair is often colored green conspicuously among men whose hair has already turned white from age or debility. The linen is regularly colored green. This staining is due to particles of copper dust coming in contact with the perspiration, and is in no sense a green perspiration. Sweating is sometimes profuse, due probably to debility, the same as the night sweats of phthisis. The eyes occasionally show hyperæmia of the conjunctiva with considerable irritability and photophobia, but only when they are subject to the direct action of the fumes or dust. In the nose, pharynx, and larynx we find the action of the copper pronounced. Examination shows intense hyperæmia, mostly dry, with only here and there a streak of mucus. The best way of describing it is to say that the entire surface looks extremely angry. The ordinary hypertrophic rhinitis appears pale in comparison and has more mucus on its surface. The patients complain of a dry, hacking cough or a feeling of constriction of the throat, that nothing relieves. The voice is often husky. The nasal irritation may cause fits of sneezing which are accompanied by profuse watery discharge, but this is exceptional. From the lungs proper we also get a dry irritating cough. Sometimes we meet a patient who says that his cough is accompanied by expectoration. This means that either he has bronchitis due to the inhalation of large quantities of dust other than copper, or that he has phthisis. I believe that in uncomplicated cases of copper irritation we have little or no expectoration. Hæmoptysis used to be mentioned as frequent, but in these days of exact physical examination this is no longer claimed to belong to copper poisoning purely. Copper certainly predisposes to phthisis; so any one with an inherited tendency to phthisis should avoid copper. On the other hand, many cases look and act phthisical that are not so. It is always necessary to have the positive physical signs, and above all elevated temperature, to call a case phthisis. I have seen patients apparently in the last stage of phthisis, and who had been told by their family physician that they had phthisis, fail to show the least trace, and have had this verified by subsequent observation. In referring to the mouth all writers dwell on the green line on the teeth. This is merely a staining green of the tartar and other impurities on the teeth, and is not to be found in persons who use the brush freely. The saliva is regularly diminished. A metallic taste is frequently complained of. The tongue may be tremulous. The stomach, being the chief port of entry of the copper, is very early affected. Loss of appetite is the first and universal symptom. Later comes more or less gastric pain. Vomiting is not common in the early stages, but in advanced cases may be so severe that the stomach retains hardly any food. The gastric secretion being below normal, the food is imperfectly digested and when passed on into the intestines causes colic. Fermentation in the intestines is common, due partly to the undigested state of the food that reaches them and partly to the insufficiency of the bile. The action of the bowels is not uniform. Constipation, diarrhœa, and normal stools may all be found. Jaundice is mentioned, but seems no more frequent than in other workmen. The kidneys again give no characteristic symptoms. Green urine is mentioned by one author, but must be rare. The circulation is regularly affected in copper workers. The common symptom is over-action of the heart with more or less palpitation. The pulse is full yet easily compressed. Much of the dyspnœa these patients complain of is accounted for by this disturbed heart action. Arteriosclerosis I have found only in those who used alcohol freely. Such symptoms as vertigo, sinking-spells, hot and cold flashes are all purely vasomotor disturbances.

We now come to certain general symptoms which are so common as to be characteristic. The face, in advanced cases, has a drawn, anxious expression as in marked phthisis. Anæmia is found in all cases. The effect of this upon the complexion is different from that of other anæmias. To me it appears several shades darker. The term sallow comes close to describing it. I know of no class of men who can be so intensely nervous as copper workers. Their restlessness is without limit. In their homes they are irritable and excitable. Sleeplessness is of course common. Itching and neuralgic pains in different parts of the body are here and there complained of. Emaciation is typical of the disease. One author calls them a "spare, unhealthy set of men." The emaciation is not confined to the subcutaneous fat but extends even to the muscular tissue. Loss of strength naturally follows such emaciation.

Diagnosis.—The symptoms that are of the greatest value in the recognition of cases of copper poisoning are: (1) dyspepsia, which is the earliest of all symptoms; (2) anæmia, which also is early and comes before emaciation, loss of strength, or painful facial expression; (3) nervousness and irritability. Add to these the fact that the patient works in copper or brass, and you cannot be mistaken.

Prognosis.—This is uniformly good when organic changes have not taken place and when a change of occupation can be effected. If the patient remains at the same work the case will go on slowly from bad to worse. It must be admitted, however, that some acquire a toleration for copper and live to be quite old. A few seem to start in perfectly immune, but these cases are so rare as to be noted exceptions. I have noticed that if copper workers acquire phthisis it is not so rapidly fatal as one would expect, and patients who receive early treatment probably show a larger percentage of cures than in other departments. Another fact to be borne in mind is that local applications to or operations upon the nose and throat for the relief of distressing symptoms are unsatisfactory so long as the patient remains exposed to the source of irritation.

Treatment.—This is first of all prophylactic. Some factories recognize the danger from copper dust and attempt to protect the men by systems of ventilating fans. Here and there a workman will protect himself by wearing a wet sponge or cloth over the nose and mouth. Both of these methods are valuable and should be encouraged. But even men who clearly see the need of taking precaution will after a time tire of it. In extreme cases of poisoning it is necessary to advise giving up the occupation altogether. Yet it must be remembered that workmen subject to chronic copper poisoning are generally skilled mechanics receiving high wages, who will not readily give up their work. Next to this I have found a vacation of from two to four weeks of the greatest benefit.

When the set of symptoms before enumerated was first discovered to be due to the presence of copper in the system, physicians instinctively turned to iodide of potassium. They reasoned that iodide of potassium is good for lead-poisoning, and therefore from analogy it must be good for copper poisoning. Any physician trying this remedy will soon come to the conclusion that it is useless. I have tried it faithfully, and know others who have tried it and given it up. The fact is, there is to-day no specific for copper poisoning. Strychnine in large doses is of value against several symptoms. It is the best stomachic and nerve tonic known, and is certainly indicated. Phosphoric acid is strongly advocated by some writers who claim excellent results. In conclusion we see that to-day our chief reliance must be prophylaxis and change of occupation. In some of the manufacturing districts of

Germany a law is in force that a man cannot work longer than three months at a time at glazing (lead poisoning). In practice this works admirably, because the men are taught to alternate with each other at their work. It would be well if this law received a wider application.

The Physiology of the Labyrinth; a New Theory of Hearing.—J. W. Barrett gives an abstract of this new theory as originally propounded by J. Rich Ewald. He calls it the "Sound-Picture" theory and gives the following as its ground principle: membranes can vibrate in very different manners. They can form a vibration type of their own when they give out their own special tone. They vibrate then in a manner similar to plates which show Chladni's figures. In the telephone and the phonograph, membranes vibrate as a whole when influenced by sound waves—that is without nodal lines. They follow the sound waves, and for this purpose must not be too thin or too flexible, and especially if they are very extensible, not too weakly stretched. Finally, they can be stretched on a frame, and if impulses act on them, they can create moving waves. If these are reflected from the frame, so that the impulse is given out from opposite ends at the same time, then the stationary waves are created which produce a characteristic picture for the given impulse. In this case, the membrane must be as thin as possible, as flexible as possible, and at least in one direction as little stretched as possible. In the ear, the impulses falling on the ground membrane create a sound-picture whose special form enables the ground membrane to create a link in the chain of the transmission apparatus, which intervenes between sound and sound sensations. This is the ground principle of the sound-picture theory, no more and no less.—*Intercolonial Medical Journal of Australasia*, August 20, 1900.

Heart Lesions following the Acute Specific Fevers.—W. A. Dickey says that success in the treatment depends more on recognizing the condition of the cardiac fibre; the size of the cavities, whether they are increased or not: if so, to what degree, the state of the vascular system, the cause or causes that may have led to the changes in the valves, if any there be, and the general health of the patient, rather than to the exact diagnosis of whether this or that valve is involved. The former are absolutely essential to correct therapeutic application, while the latter, however much desirable from a diagnostic point of view, is not vitally necessary—so long as we have compensation—which, however, may be very soon and easily lost—an effort should be made to keep the cardiac fibre in a good state of preservation by improving the patient's nutrition and regulating his habits of life.—*Chicago Medical Compend*, October, 1900.

A Method of Hand Disinfection.—J. Hahn has used the following method with success and believes it possesses advantages over those in general use. The hands and forearms are scrubbed with common yellow soap and water at a temperature of about 104 F. with a boiled brush, the water being changed four times, and sufficient soap used to make a lather. After the second scrubbing the nails are cleaned and trimmed. The washing is then continued for four minutes with an alcoholic one-per-cent. bichloride solution which is rinsed off in a one to two per cent. aqueous solution of the same agent (for one to two minutes) and they are finally again immersed in the alcoholic solution after the operating-gown has been put on.—*Centralblatt für Chirurgie*, October 6, 1900.

Purulent Frontal Sinusitis in Ozæna.—G. Ricard reports the case of a woman aged fifty-two years, on whom the Ogston-Luc operation was performed with relief of the sinus trouble while the ozæna remained stationary. The case brings out the following facts: Transillumination may give no shadow in the region of the frontal sinus even when it is full of pus, for clearness depends not on the possible contents of the sinus but on the thickness of its lining walls. The destruction of the orbital wall by suppuration does not prevent immediate union of the wound and drainage by the nasal passages. Finally, cure of the sinus disease does not necessarily imply that of an accompanying ozæna.—*Revue Hebdomadaire de Laryngologie*, September 22, 1900.

Nasal Polypus.—L. Rehti reports a case of nasal polyp remarkable in that its size caused considerable increase of the width of the nose from intra-nasal pressure. This latter feature, while common enough in various intra-nasal tumors, is yet rare in ordinary polyps. The polyp in this case measured four inches in length, was pear-shaped, and had a circumference of somewhat over four inches at its greatest diameter. In general appearance it suggested a fibroma presenting various furrows on its surface, with ulcerated areas and some hemorrhagic spots. Microscopical examination showed it to consist of areolar connective tissue in an œdematous matrix, with here and there some few fibres of harder tissue.—*La Parole*, July, 1900.

The Surgical Treatment of Anasarca.—After medical measures have failed, Menok advises surgical intervention for the relief of the œdema of the extremities accompanying cardiac or renal diseases. In spite of the apparent simplicity of the manœuvre the risk of maceration of the skin and subsequent infection have always been considered so great that it has never found favor as a routine treatment, but with care and the adoption of aseptic precautions the danger from these causes may be reduced to a minimum. Of the various procedures that have been suggested the two most useful are incision and drainage. The former of these is to be used only in restless or delirious patients, or in those whose dyspnœa prevents the recumbent posture, for it favors infection to a much greater degree than the less radical operation. The difficulty lies in keeping the incisions closed and so preventing the continual oozing of fluid, which not only renders the patient uncomfortable through the saturation of his bedding but prevents the healing of the wounds, and by the tendency of the fluid to undergo ammoniacal fermentation irritates and macerates the skin, making it a suitable culture ground for bacteria. The method of drainage is not open to these objections, and has the further advantage that the flow may be easily checked at any time that weakness or collapse on the part of the patient makes it desirable. The author employs a slightly modified Curschmann's cannula, which after careful sterilization of the skin is plunged into the subcutaneous tissue and may then be connected to a rubber tube which conveys the fluid to a vessel at the bedside. Anæsthesia may be dispensed with, for the tension renders the skin insensitive, and the only inconvenience attending the operation is the necessity it enforces upon the patient of remaining quiet in bed for from eight to ten hours, longer than which time it is not advisable to leave the instrument in place. If further drainage is required, a fresh puncture should be made to diminish the damage to the tissues and their consequent vulnerability to germs. To seal the puncture a strip of iodoform gauze kept in place by a special spring compress is the most suitable dressing, and may be removed at the end of three days, at the expiration of which time closure is usually perfect.—*Wiener klinische Rundschau*, October 7, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PUBLIC SPEAKING IN THE MEDICAL PROFESSION.

PUBLIC speaking is of various kinds. A wide gulf divides the high flights of oratory of a Bright or a Webster, which can excite the passions or sway the emotions and control the moods of a vast audience, and the scintillations of wit which flash from a Mark Twain or a Depew, and which are so admirably calculated to promote digestion and to induce that comfortable feeling of well-being ever the desired sequence of a satisfactory repast. There is much difference between the lecture on some abstruse scientific subject, delivered by a learned professor, and the plaintive appeal of a philanthropist on behalf of charity. But it matters not what the manner or matter of the speech may be, the object to be attained in every description of public speaking should be to express the thoughts in words as clear and comprehensible as possible. Orators are few and far between, and many think that to possess a fervid, burning eloquence, which by its mere exercise will render its possessor a power in the land, is to have a touch of the divine spark, and that such a man is, like a poet, "born and not made." Although great orators at the present time can be counted upon the fingers of one hand, happily very excellent public speakers abound. And the fact must also be taken into account, that the conception of a great orator now prevailing would not be altogether in accord with the views taken on the same subject years ago. It is more than likely that were Demosthenes or Cicero to revisit this earth, the charm of their eloquence would fail to conquer as of yore, and that even Gladstone would not be appreciated as he was thirty years ago. So far as physicians are concerned, it goes without saying that for them to shine conspicuously as speakers they must be endowed with similar gifts and perfected by the same amount of practice as are men in other lines of life. It is asserted, and it would appear with a substantial basis of truth, that physicians taken as a class do not compare favorably in the art of public speaking with those who follow some other vocations. This may be put down to a lack of training and of practice.

Dr. William Whitford, official stenographer of the American Medical Association, published in the *Journal* of that association for September 22d an article treating of the physician as a speaker. The article in question deals with the subject from all standpoints, but especially from that of the reporter. It is shown that the pitch, intensity, and amplitude of a speaker's voice have much to do with the work of the reporter, in that they will greatly expediate his work or render it extremely difficult. It is an irksome task for any reporter, no matter how acute his hearing may be, to follow a physician who has a low-pitched, thick voice, coupled with a mumbling mode of utterance. On the other hand, remarks Dr. Whitford, the physician who takes cognizance of acoustics and pitches his voice in a much higher key, if he articulates well, can be heard in the remotest nook or corner of a large convention hall without apparently unusual effort. A low-pitched voice, combined with rapidity and indistinctness of utterance, will worry most reporters. A physician with a tolerably high-pitched voice may be clear and distinct in utterance yet excessively rapid in delivery. His clear-cut sentences may flow uninterruptedly at the rate of between one hundred and sixty and one hundred and ninety words per minute. Such a man can be reported with comparative ease by an efficient hand. Many suggestions and hints are advanced to would-be-speakers, which, of course, are as applicable to men of any other calling as to physicians, but as it may be assumed that the writer has gained most of his experience in reporting the speeches of members of the medical profession, his advice may be taken to themselves.

Perhaps the most personally interesting portion of Dr. Whitford's article is that in which physicians and lawyers are compared as speakers. After pointing out that the art of speaking well is not confined to statesmen, jurists, and clergymen, and that the medical profession, like the ministerial and legal professions, has orators within its ranks, he goes on to say: "I have had the pleasure of reporting the utterances of several eminent lawyers from time to time, and to speak candidly, I must confess that they were not the superiors in any sense of many of the physicians whose impromptu speeches I have reported." As striking examples of the extemporaneous type of speakers in the medical profession the following three are cited. Dr. Nicholas Senn is referred to as a fluent, forcible, and impressive speaker with an excellent command of language, who possesses a richness in his diction, a copiousness, ease, and variety in his expression, which are rarely surpassed by the best extemporaneous speakers. In debates he shows to best advantage when under heavy fire, and is a master of repartee. Dr. Charles A. Reed, of Cincinnati, is presented as a splendid specimen of the scholarly, well-read speaker, who is chiefly distinguished for his elegant diction and the ornateness of his phraseology, and Dr. Joseph M. Matthews, of Louisville, Ky., is given as a shining example of the easy, graceful, polished speaker, whose forte is simplicity of language.

No one can deny these conclusions or refuse the due meed of praise to the above-named speakers, but it must also be borne in mind that while the West has every reason to be proud of her elegant medical sons, yet the East has at least no cause to be ashamed of

the physicians within her borders who are gifted with considerable rhetorical powers.

In the first place, however, it must be said that the character of the speech-making of doctors in the East and West differs in most instances in many important particulars. The speakers of the West, including the medical speakers, would appear to be greatly influenced by the size, the width, and breadth of their country; the air of the illimitable prairies would seem to have permeated their systems and to have perhaps unconsciously imparted to their speech some of its breezy vastiness. On the other hand, the manner of public speaking in the East is founded more upon the British style, less copious and diffuse, more reserved than the oratory of the West, but quite as much to the point. Dr. T. Gaillard Thomas, Dr. D. B. St. John Roosa, Dr. William H. Draper, of New York, Dr. Osler, of Baltimore, Dr. Weir Mitchell and Dr. Keen, of Philadelphia, are physicians who may be relied upon to uphold the honor of the United States as speakers in any company. Some may think that to say that public speaking in the East is founded upon the British style is not to pay public speaking in the East a distinguished compliment.

We certainly do not intend to convey the impression that we think public speaking anywhere in the United States is slavishly modelled on British lines, for the American style of oratory is peculiarly its own and in many respects quite superior to that of any other country. There is generally in the speeches of a typical American speaker, be he doctor or otherwise, a fund of dry, caustic, but withal good-natured humor which is unattainable by the orator of Europe. However, the fact must be confessed with some degree of shame, that neither in this country nor in Europe are doctors in the front rank of public speakers. Some of the more prominent here have been mentioned. In Great Britain, perhaps, at the present time, Sir William McCormac is the best medical public speaker, in Germany Virchow and von Bergmann stand at the head, in France Lannelongue leads, and in Italy Durante. The United States can lay claim to a medical man who, as an after-dinner speaker, was probably never surpassed, the inimitable Oliver Wendell Holmes, and Great Britain possessed in the late Sir James Paget an orator who could vie with the greatest that country ever produced.

Before leaving the subject it may not be presumptuous to suggest to the young physician that, in public speaking, he should always be terse and to the point; needless redundancy of language should be avoided as the plague. The speaker who is "inebriated with the exuberance of his own verbosity" will surely lose himself and his audience in a hopeless maze of words. Physicians should cultivate the art of public speaking. If they do so they need fear no comparison with either statesmen, or lawyers, or ministers.

Displaced Tendons.—The tendons most liable to displacement from violence are the peroneus longus at the outer ankle and the long head of the biceps, which may slip out of the bicipital groove.

THE DIFFERENTIATION FROM RUBELLA AND SCARLET FEVER OF A DISEASE RESEMBLING BOTH.

The disorder variously known as rubella, Rötheln, German measles, French measles, roseola, epidemic rose-rash, has ever been a source of confusion in diagnosis with reference to both scarlet fever and measles, with each of which it possesses certain features in common; but the prevailing opinion is that it represents a distinct entity and not a mixture of these two other diseases. The decisive fact in this connection is the failure of any one of the diseases to confer immunity to any of the others. The difficulties of the situation will, however, not be lessened by the announcement recently made by Dukes (*Lancet*, 1900, No. 4.011, p. 89) that what has hitherto been looked upon as rubella consists probably of two distinct diseases—a fact that suggested itself several years ago, but conclusive evidence in favor of which has been obtained only recently. For the new disorder the designation of fourth disease has, by reason of its resemblance to rubella, scarlet fever, and measles been tentatively proposed, and this may be wisest until its position has been established beyond peradventure. The differentiation between rubella and the fourth disease would, however, appear by no means easy, as both present similar symptoms; both frequently occur in the same locality at the same time, and the period of incubation is much alike in both.

The fourth disease, it has been found, is in many cases unattended with premonitory symptoms, although there may be pronounced malaise for some hours, with headache, anorexia, drowsiness, chilliness, and even backache. Like rubella, it occurs especially in the spring and summer. The period of incubation is estimated at from nine to twenty-one days. A diffuse rash appears upon the surface of the entire body within a few hours after the inception of the disease. The exanthem is bright rosy-red in hue, and somewhat raised above the contiguous surface. The sensation of heat conveyed by the skin to the finger is, however, less than in scarlet fever. The fauces are usually swollen and reddish, assuming a velvety appearance. The conjunctivæ are pink and suffused. The lymphatic glands universally are enlarged, hard, and tender, feeling like peas, though less manifest than in rubella; those mainly affected are the post-cervical, the axillary, and the inguinal. Desquamation may be slight or marked, but it bears no constant relation to the intensity of the rash. The kidneys are rarely involved. There is, as a rule, no marked sense of illness. The tongue is clean or slightly furred. The pulse may be normal, but it is proportionate to the temperature. It varies between 98.4° and 103° or 104° F., and it bears no relation to the extent of the rash. The symptoms, even if severe, subside in the course of a few days, leaving comparatively little feeling of illness. The fourth disease has been found to be not profoundly infective in its earliest stage. At a later one, even while desquamation is taking place, it is not infective beyond two or three weeks after thorough disinfection. There are practically no

sequelæ, although the submaxillary glands may remain enlarged. The disease usually terminates in complete recovery within three weeks.

It will be seen that the symptoms described do not afford a ready means of diagnosis from rubella. The rash of the latter, however, is at first punctate, subsequently becoming coalescent and forming bats' wings, in contradistinction from the diffuse exanthem of the fourth disease. Further, rubella is said to be by far the more infective disease. On the other hand, apart from the significant fact that one attack of either disorder does not confer protection from attack by the other, the points of differentiation are not so clear as to justify final acceptance of the individuality of the disease without further confirmation. As compared with scarlet fever the period of incubation of the fourth disease is longer; premonitory symptoms are wanting; the pharyngeal manifestations are slight; the pulse is not greatly accelerated; the tongue does not peel; the period of infectivity is shorter; the kidneys are not involved, and one attack does not confer immunity from scarlet fever. The importance of accuracy in diagnosis must be obvious, as failure to recognize scarlet fever may be attended with disastrous results, and the mistaking of the fourth disease for scarlet fever would cause the patient to be subjected to unnecessarily prolonged isolation.

A MEDICAL DEFENCE ASSOCIATION FOR MINNESOTA.

In an editorial published in the Medical Record September 15th, the efforts being made by Dr. Donald B. Pritchard and others to establish a medical defence association were favorably commented upon. It was further suggested that such a plan intelligently carried out might be followed with advantage in all parts of this country. We now learn that Minnesota has incorporated a medical defence union. Its membership is confined to residents of Minnesota who are members of the State Medical Society or societies auxiliary to it. The annual dues are fixed at $5, and each one pledges himself to pay $10 if called upon to do so by the directors. The association binds itself to defend and pay all the costs of defence in the event of any of its members being sued for malpractice, when, after proper investigation, the directors are satisfied that the case is a good one. It does not purpose to aid those guilty of malpractice, but simply to defend against blackmail.

Dr. Wiggins contributed a letter to the Medical Record of September 29th, in which he advocated that the State societies should make the defence of suits brought against their members for malpractice a part of their work. Where workable this would seem to be the most rational and easiest manner of settling the question, but it is argued that the State societies do not care to take up the matter, and that defence associations working in close touch with their respective State societies can accomplish a great deal. In those cases in which State societies are disinclined to act of their own initiative, the example set by Minnesota might be profitably imitated; that is, by making membership in these societies a prerequisite of membership in the defence associations. At any rate the scheme of a medical defence association established on the lines of that of London is worthy of trial, and Dr. Donald Pritchard and his coadjutors in Minnesota are deserving of praise for setting "the ball rolling" in this direction.

News of the Week.

Disease in the Yukon. — A despatch from Seattle says that the Rev. Father John B. Rene, in charge of the Roman Catholic missions on the Yukon, has arrived at Dawson with a terrible story of the sufferings of the natives in that valley from an epidemic of a mysterious disease resembling a combination of pneumonia, measles, and typhoid fever. At Holy Cross mission sixty out of one hundred and fifty Indians died in less than two months. Famine now threatens, as the natives have not been able to lay up supplies of fish and game for the winter. The epidemic, whether it is of plague or some other disease, has been general all along the river and along the coast of Bering Sea, and thousands of natives have died, and it is feared that many more will die from the disease itself or the starvation following in its train.

Philadelphia Neurological Society.—At a stated meeting held October 22d, Dr. David Riesman exhibited a case of probable cerebellar tumor, in a man presenting staggering gait, increased knee jerks, lateral nystagmus, pallor of the optic discs, and vertigo in the erect posture. Dr. William G. Spiller exhibited a case of progressive ascending unilateral paralysis, in a man presenting symptoms of unilateral spastic paraplegia, without history of an apoplectic seizure or of any loss of consciousness. Dr. Spiller exhibited also a case of multiple neuritis of the upper limbs, probably the result of hydrofluoric-acid poisoning, in a man who had been engaged in one of the processes of etching on glass, and had developed swelling of the hands and arms, followed by wrist-drop and paresis in both upper extremities. It was thought that neuritis might have developed from absorption of some poison, such as hydrofluoric acid, through the skin, although the possibility of absorption through the respiratory tract was suggested. Dr. James Hendrie Lloyd exhibited a case of Bell's palsy associated with complete anæsthesia in the territory of the fifth nerve. The patient was a young woman, and the lesion of the seventh nerve was attributed to exposure to cold, while the disturbance in the distribution of the fifth nerve was thought to be hysterical. Dr. Charles S. Potts exhibited a case of left hemiplegia with right facial palsy. The patient was a young man presenting central paralysis of the left side of the face and peripheral paralysis of the right side. In emotional movement the action of the left side of the face preponderated, while in active movement the action of the right side was the more

pronounced. Dr. F. Savary Pearce exhibited a case of unusual trauma with secondary Bell's palsy. The patient was a young woman who had been struck upon the head or face, with the result that the tip of a pipe-stem became embedded beneath the skin on the right side of the neck behind the ascending ramus of the lower jaw, probably injuring the seventh nerve by contiguity. Dr. Clarence Van Epps read an admirable paper on "The Babinski Reflex."

A Prison Hospital at Dannemora.—A new hospital for insane convicts has been erected for Clinton Prison, most of the work on it having been done by the convicts. The building is three hundred feet long by forty wide, and will be ready for occupancy in November. It will relieve the overcrowding at Matteawan Hospital.

Payment for Illegal Practice Refused.—A physician practising in the Province of Quebec made a contract some time ago to render professional services in one of the United States whose laws debarred him from engaging in the practice of medicine there. The contract was broken by the other party to it, and the doctor brought a suit against him, in the Canadian courts, to recover the value of the work which he had done under the agreement. The defendant interposed a defence setting up the illegality of the contract, as being an undertaking on the part of the plaintiff to practise medicine and surgery in a foreign State where it was unlawful for him to practise. This defence has finally proved successful, the court holding that no compensation is recoverable upon a contract of this character, which is pronounced illegal.

Preliminary Announcement.—The ninety-fifth annual session of the Medical Society of the State of New York will be held in Albany, January 29, 30, 31, 1900. The meetings of the society have always been replete in scientific work as becomes the representative society of the medical profession of the Empire State, and it is confidently expected that this meeting will equal those which have preceded it. This circular letter is sent to every member of the society with the request that those who desire to read papers will communicate at once with the chairman of the business committee, Dr. Frank Van Fleet, 63 East Seventy-ninth Street, New York City, or with the president, Dr. A. M. Phelps, 62 East Thirty-fourth Street, giving the title of the paper and such other information as the author desires. As there will be a great many papers offered, and the time necessarily limited, it is suggested that papers be condensed as much as possible in reading, as they can be published more fully in the Transactions. Arrangements for reduced fares can be made when purchasing railroad tickets. A. M. Phelps, M.D., president.

The Craig Colony for Epileptics.—The board of managers of the Craig Colony at Sonyea, Livingston Co., N. Y., held their seventh annual meeting at the Colony on October 9th. Dr. Frederick Peterson, of New York, was re-elected president, and Mr. H. E. Brown, of Mt. Morris, secretary. The report of the medical superintendent, Dr. William P. Spratling, showed that there were six hundred and twelve patients in the Colony on October 1st last. The total capacity of the Colony, including the new buildings nearly ready for occupancy, is eight hundred and forty, and it is expected that the Colony will have that number by July 1, 1901. Ultimately the Colony will be inhabited by eighteen hundred or more. The managers decided to ask the coming legislature for $169,000 for new buildings and other improvements, and for $125,000 for maintenance. Of the money asked for special purposes, $98,000 will be used for dormitories for patients. The superintendent called attention to the fact that thirty-six out of six hundred and twelve patients at the Colony are suffering from tuberculosis in some stage, and he recommended that suitable wooden barracks be constructed as soon as possible, in order that these patients might be isolated. It is possible to do this on account of the vast size of the Colony estate. The superintendent called attention to the great necessity for providing better means of transportation on the Colony, and advocated the construction of a trolley system, the power for which already exists at the Colony. A resident pathologist, at a salary of $2,500 a year, with maintenance, will soon be appointed.

The End of the Glasgow Plague.—The last of the plague patients was discharged from hospital in Glasgow on November 3d.

Suit against Insane-Asylum Officials.—A Chicago man, recently released by order of the court from an insane asylum, has brought suit for $250,000 damages against the superintendent and other officers of the asylum. He alleges that he was illegally detained.

Dr. Senn's Gift to a Medical College.—Rush Medical College in Chicago is to have a new $80,000 building, for which Dr. Nicholas Senn has just given $50,000. The new building will be principally used for clerical purposes, and will be named Senn Hall.

A City Plague Laboratory.—The New York City board of health, at a recent meeting, awarded a contract for the building of the laboratory for the study of the bubonic plague on the Willard Parker Hospital grounds at the foot of East Sixteenth Street. The cost of the building will be $19,893. The laboratory is to be built in three months.

The September Mortality in this State.—The New York State board of health bulletin, issued November 2d, shows a total of 10,251 deaths during September in the State, representing an annual death rate per thousand of population of 16.5. Of this number 245 deaths were caused by typhoid fever and 930 by consumption.

The Medical Inspection of Prostitutes.—It is stated in the *Cleveland Journal of Medicine* that the health board of Columbus, Ohio, has ordered the weekly inspection of prostitutes by the district physicians. This, of course, is being done in the hope of controlling the spread of venereal disease. A very curious difficulty has arisen in consequence of this order. It

seems that certain physicians have been conducting such examinations under contract with the proprietors of the houses of prostitution. They, therefore, object to the curtailing of their practice by the city putting the matter into the hands of the district physicians.

A City's Right to Establish Pest Houses.—A suit was recently brought against the city of Chicago by the owners of land near the smallpox hospital, opened by the municipal authorities on Lawndale Avenue in 1896, to recover damages alleged to have been sustained by their property in consequence of the proximity of this institution. The plaintiffs have been finally defeated in the supreme court of Illinois. It was not asserted that the city had been negligent in the care and conduct of the hospital, or that it was any more of a nuisance than such an institution must be of necessity. The supreme court held that there is no difference in principle between the right of a municipality to establish a pest house and its right to build a jail or fire-engine house.

The Fight over the Tuberculosis Hospital Site.—The efforts by the residents of Clinton County to induce the State authorities to erect the proposed hospital for the treatment of incipient tuberculosis at Dannemora, and their opposition to the selection of a site at Lake Clear, have aroused the residents of the Saranac Lake region to vigorous protest. At a recent meeting resolutions were adopted and ordered to be forwarded to the State board of health and the forest preserve board, by whom the site is to be selected. These resolutions indorse the selection of the Lake Clear site and condemn that of Dannemora. They object to the latter on the ground that "the surroundings in a penal colony are incompatible with cheerfulness" and "have a tendency to produce melancholia, a condition most to be avoided in tuberculous patients." They also object to the employment of convict labor, which would be used in the construction of the buildings if the latter were erected at Dannemora.

A New Medical Association.—A committee of the El Paso County (Texas) Medical Society has issued invitations to the members of the regular medical profession of Texas, New Mexico, Arizona, and Mexico to meet in El Paso on the occasion of the El Paso midwinter carnival on the 17th day of January, 1901, for the purpose of organizing a tri-State or territorial medical association. Volunteer papers are requested from all who are willing to contribute, and such are especially requested to send in their names and the titles of their papers at the earliest possible date, that the programme may be completed and sent out in due time. The members of the committee are Drs. S. T. Turner, W. N. Vilas, and F. W. Galagher.

Local Health Boards in Louisiana.—We learn from the *New Orleans Medical and Surgical Journal* that twenty-five new health boards have recently been established in Louisiana. The bill which was passed at the last session of the legislature, providing for the establishment of parish boards of health throughout the State, makes it obligatory on the police of every parish to organize a parish board of health. Formerly the law required the physicians to live in a parish five years before they could become members of the board, but now residence of one year as a registered voter in a parish is sufficient for membership on such board of health.

A Plague Suspect in Bremen.—A despatch from Bremen states that a sailor who arrived there October 27th on board a German steamship from South America was taken ill with suspicious symptoms, and the authorities have notified the bacteriological experts to determine whether it is a case of the plague.

A Famine Threatening in Russia.—A correspondent of the London *Daily Mail*, writing from St. Petersburg, says that, in spite of official denials, there is no doubt that the inadequate harvest will produce a famine in the governments of Kherson and Bessarabia.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending October 27, 1900. October 19th.—Passed Assistant Surgeon D. H. Morgan commissioned passed assistant surgeon from November 27, 1899. October 22d.—Assistant Surgeon R. E. Ledbetter appointed assistant surgeon from October 19, 1900.

The "Decinormal" Salt Solution.—We receive from time to time letters inquiring why the saline solution used for intravenous injection is called "decinormal." The reason is, as was explained by Dr. J. B. Nicholas, of Washington, in the MEDICAL RECORD of August 14, 1897, that a normal solution in volumetric chemistry is a solution containing in 1,000 c.c. an amount of the active constituent just sufficient to combine with or replace 1 gm. of hydrogen. In the case of sodium chloride this amount is 58.37 gm., hence a normal saline solution is one containing 58.37 gm. to the litre of water. A solution one-tenth of this strength (a "decinormal" solution) contains 5.837 gm. to the litre, which is just about the strength of the saline solution used for venous infusion.

The Late Dr. S. S. Purple.—The president and fellows of the New York Academy of Medicine hereby express their high estimate of the character of the late Dr. Purple, as a citizen and a physician; their earnest appreciation of his valuable services as a fellow and an officer of the Academy, and their grateful acknowledgment for rare books and pamphlets presented by him in large numbers to the library of which he was the founder. They earnestly desire to extend to the members of his bereaved family their profoundest sympathy in this, the hour of their sad affliction. WILLIAM H. THOMSON, M.D., president; LOUIS F. BISHOP, M.D., secretary.

A committee consisting of Drs. Jacobi, Stephen Smith, Elsworth Eliot, and J. D. Bryant, appointed by the Academy to consider a suitable recognition of the services of Dr. Purple, duly reported as follows:

That on account of his beneficent act in founding the library, and because of other significant aid to the Academy, it is recommended that a tablet suitably inscribed be erected in the Academy, and that a fellow

be appointed by the president to deliver a eulogy on the late Dr. Purple at the time of its unveiling.

Obituary Notes.—Dr. Matthew J. Grier died at his home in Philadelphia on October 27th at the age of sixty-seven years. He was graduated from the Medical Department of the University of Pennsylvania in 1863, and at once entered the medical service of the Union army and served until the close of the war.

Dr. Michael Kelliher, of Pawtucket, R. I., died on October 31st. He was a graduate of the New York University Medical School in the class of 1866.

Dr. Louis W. Read died at his home in Norristown, Pa., on November 1st, at the age of seventy-two years. He was born in Montgomery County, Pa., in 1828 and graduated from the medical department of the University of Pennsylvania in 1849. When the Crimean War began he offered his services to the Russian government, was accepted, and served throughout the war, effecting important improvements in the treatment of gunshot wounds, which were afterward adopted in the United States and Europe. In 1861 he was appointed surgeon on the First Pennsylvania Reserves and later was made surgeon of the United States Volunteers. In 1864 he took charge of the McKean Hospital in Baltimore, where he served two years.

Progress of Medical Science.

Boston Medical and Surgical Journal, Nov. 1, 1900.

Gunshot Injuries by the Rifles of Reduced Calibre.—Louis A. La Garde discusses the effects of the seven-millimetre Mauser rifle as observed by him among fourteen hundred wounded in the Spanish-American war. The wounds of entrance and exit and the narrow track of the missile favored rapid healing, and infection was seldom noticed. Of the fourteen hundred wounded none died of external hemorrhage, nor was it necessary to ligate a vessel for alarming hemorrhage on the field. The gunshot injuries of the diaphyses were as a rule attended with but little comminution. In wounds of the principal joints, including epiphyses, clean-cut perforations without fracture were the rule. Of thirty-one cases of gunshot injury of the head, 58.1 per cent. ended fatally. Fifty-three penetrating wounds of the thorax were observed, with a mortality of 24.5 per cent. Penetrating gunshot wounds of the abdomen were very fatal. Of forty-one recorded cases twenty-nine ended fatally. The value of skiagraphy and the use of the fluoroscope were exhibited in locating missiles, in determining the extent of bone lesion, in detecting supposed cases of guttering or perforation of the long bones without fracture, and in probable lesion to nerves and tendons by loose spicula of bone.

Phthisis. Some Causes of Failure in its Climatic Treatment.—Will Howard Swan urges three points to be remembered by physicians if they would have their consumptive patients benefited by the climate of Colorado: (1) Do not send patients with far-advanced phthisis unless they are able to make the change without serious fatigue, and unless they can live there in the manner they should and for a prolonged period. (2) Do not send early cases unless there are assured means for proper hygienic living for a period sufficiently long to get the patient well enough to earn, in part at least, his living, and to find employment. How long this will be will depend upon the individual case and his progress, but, roughly speaking, three or four months at least. There are many openings for employment, but more people looking for the desirable ones. (3) Most important of all, instruct the invalid to rest and to keep quiet after his arrival until some one competent to advise him considers it safe to begin to exercise; and then have his manner of life and hygiene directed from time to time, according to his progress and condition.

Eye Strain as a Cause of Gastro-Intestinal Neuroses.—M. P. Smithwick calls attention to eye strain as one factor to be considered in searching for the cause of a gastric or intestinal neurosis, and reports a number of cases in which indigestion, nausea, vomiting, headache, etc., were relieved by the wearing of appropriate glasses. Of 20 cases representing various types of digestive neuroses, eye symptoms other than headache were present in 7; headache was a symptom in 20 cases, all having eye defects. Eye defects were found in 18 out of the 20 cases and glasses given. Fifteen patients had astigmatism, 13 hyperopia, and 2 compound. Of these 15 cases 5 patients had also hypermetropia, 3 muscular trouble, 1 axis "against the rule," 1 opacity of a lens, 2 diminished vision. Two cases only had hypermetropia and 1 myopia.

Purpura Hemorrhagica, or Morbus Maculosus of Werlhof.—By Stephen Smith Burt.

A Note on Rectal Feeding in Peptic Ulcer.—By George G. Sears.

Achlorhydria; its Effects and their Treatment.—By H. F. Hewes.

Journal of the American Medical Ass'n, Nov. 3, 1900.

Connell's Operation of End-to-End Anastomosis of Small Intestine for Repair of Enterotomy Performed to Relieve Acute Obstruction; First Case Reported on Human Subject.—Franklin H. Martin reports this case. After describing the preliminary steps of the operation, the writer states that two or three inches of the small intestine were excised on each side of the opening which formed the artificial anus, so that about five inches of the gut were removed. The intervening mesentery was tied in three sections. The end of the gut representing the part above the artificial anus was larger than the coil below that point. The smaller end was incised obliquely in order to increase the diameter of the free end, which was accomplished at the expense of its convex border. The end-to-end anastomosis after the method described by Dr. F. G. Connell was then performed. The method, although easy to execute, is not easy to describe, and the writer points to his illustrations in order to assist the reader. "This method consists of a modification of Maunsell's procedure, the original feature of importance being the ingenious method of tying the last suture in a way which effectually places all knots on the mucous surface of the bowel without the necessity of making the ordinary extra incision employed in Maunsell's operation." The intestine after the operation looks much like the end-to-end anastomosis with the Murphy button. There are no sutures visible between the approximated serous surfaces, although all coats of the bowels are included. The writer believes this operation to have all the advantages of the Murphy button with none of its serious faults. The time consumed in the anastomosis was between fifteen and twenty minutes. Convalescence was uninterrupted.

Hypertrophy of the Pharyngeal Tonsil; its Anatomy and Physiology.—After speaking of the anatomy and physiology of the pharyngeal tonsil, Norval H. Pierce states that adenoids are hyperplasia of this normal tissue. They vary in size, consistency, and color. The infectious diseases, especially measles, scarlet fever, etc., play an important rôle in the causation of this condition. Acute inflammations of the gland frequently cause acute hyperplasia. The question of the dependence on tuberculosis is not yet definitely settled. The writer does not believe that Dansac's varieties, the scrofulous, tuberculous, and syphilitic, comprise all the varieties of adenoids. Many scrofulous children have adenoids, and many who show no evidence of scrofulosis or chlorosis have these bodies in their postnasal spaces. Abscesses may develop in this tissue which may cause septic meningitis. Cysts, and all of the tumors, especially sarcoma, develop from the membrana prevertebralis.

Receptive Quiescence of the Stomach during Mastication; Gastronomic Phenomenon Not Previously Described.—Evan O'Neil Kane describes this case on which he had operated, performing a gastrostomy. The patient was gradually starving from stricture of the œsophagus due to cancer at the cardiac orifice of the stomach. Great difficulty was experienced in applying the retaining pad before peristalsis caused the rejection of the fluid food which was introduced into the stomach. It was observed that when the patient was chewing anything while he was fed, his stomach would remain quiet, so that the pad could be placed before muscular activity recommenced. Chewing-gum was used, and no more difficulty was experienced.

A Case of Sudden Death, Probably due to Pulmonary Embolism.—The patient of J. S. Horsley was a farmer aged thirty-two years, who suffered from stone in the bladder. A suprapubic cystotomy was done, and the patient did well for three days, when symptoms of suppression occurred. Under the administration of large quantities of distilled water and milk, with some digitalis, these symptoms entirely disappeared, and the patient advanced in convalescence uninterruptedly until the day he was allowed to sit up. He felt perfectly well, and the wound was in excellent condition. The nurse carefully lifted him to a sitting posture in bed, when he suddenly gasped, turned purple in the face, and complained of pain in the region of the heart. The doctor was summoned by telephone, and reached the patient in five minutes. The heart was faintly fluttering and his face still bluish. His heart stopped entirely within seven minutes from the time of the attempt to sit up. Unfortunately, it was impossible to obtain a necropsy.

Modern Cæsarean Section; an Ideal Method of Treatment for Placenta Prævia.—A. P. Dudley believes that this plan of caring for placenta prævia is one which is fully justifiable and which offers greater safeguards than those hitherto followed, when all the factors in the case are taken into account. He describes his method of operating in detail, one important feature being the constant irrigation of the field with a warm saline solution. He does not believe that the patient is subjected to any greater danger of infection than those which follow in the wake of forcible introduction of the whole hand into the vagina, rapid manual dilatation of the uterus, turning and forcible extraction of the child, living or dead, and the consequent lacerations that must certainly attend such a procedure. He refers to the experience of others with placenta prævia in general.

A Case of Paralysis of the Recurrent Laryngeal Nerve; Recovery.—J. F. Culp's patient was a man aged thirty-six years, in whom a sudden loss of voice came on while smoking and talking. When seen some three weeks later acute laryngitis was found with the left cord in the cadaveric position. A diagnosis of probable neuritis of the recurrent nerve was made. Abstinence from tobacco and rest of the larynx were ordered, with sprays of menthol and benzoinol. Later the constant current was applied to the neck. Nux vomica was given as a tonic and checked a diarrhœa from which the patient had suffered for some years. At the end of six months his voice was normal and examination showed a perfect larynx.

Obervations upon the Quartan Malarial Parasite and upon the Staining Reactions of the Tertian, Quartan, and Æstivo-Autumnal Parasites.—According to the statement of Charles F. Craig, of nearly two thousand cases of malaria, the records of which have been preserved, and in which the malarial parasites were present in the blood, only twelve quartan infections were noted. This parasite is as distinctive in its morphology as is the tertian or æstivo-autumnal variety. In twenty-four hours the distinguishing features are fully developed. The organism is sharply cut and looks often as if it were stamped into the blood corpuscle; it is refractive, and its protoplasm often presents a peculiar, finely granular appearance; the pigment is dark brown, in the form of rather coarse granules, and is generally collected around the edge of the organism; the pigment is motionless. The shape of the organism at this stage is usually triangular, ovoid, or round, and it is not amœboid. The invaded corpuscle is smaller than the healthy ones and is of a darker green color. The writer then describes Romanowsky's, Chenzinsky's, and Futcher's methods of staining.

Treatment of Puerperal Eclampsia.—J. B. Killebrew gives the following order of procedure in the treatment of puerperal eclampsia: (1) Control convulsions with chloroform; (2) bleed the patient and give intravenous injection of decinormal salt solution; (3) empty the uterus. If the number of competent persons present is sufficient, the last two methods can be practised with benefit at the same time. After these measures the colon should be thoroughly irrigated. Many physicians have had good results with veratrum viride. Pilocarpine is dangerous. Morphine should not be used on account of its effects on the various secretions. Since the mortality so far in this affection has been about twenty-five per cent., there is yet room for improvement in the methods of treating it.

Is Living Animal Tissue Capable of Neutralizing the Effects of Strychnine and Venom? An Experimental Study.—S. J. Meltzer and G. Langmann summarize their results as follows: Constriction of an extremity of an animal, even after removal of the constriction, markedly retards the fatal outcome of snake poisoning and transforms an effective minimum dose of strychnine into an ineffective subminimum dose. This effect is apparently due to some impairment of the power of absorption within the constricted leg. It seems quite certain that no part of either poison becomes fixed or neutralized by the tissues of the animal experimented upon. The claim of v. Czyhlarz and Donath to that effect could not be sustained.

Subarachnoid Injections of Cocaine as a Substitute for General Anæsthesia.—In concluding his paper on this subject, A. M. Phelps declares that these experiments should be done by men of mature judgment, of long experience, of clear heads. He thinks, as long as ether and nitrous-oxide gas have so low a mortality, the profession should be loath to substitute another method which must necessarily have a great mortality. Two deaths occurred in Paris this summer from this method of administration of cocaine. On this side the water there are occasional reports of a death or of alarming symptoms following this method.

A Note on the Use of Nitrous Oxide and Ether as an Anæsthetic.—Thomas R. Brown and Howard A. Kelly have for the past eight months been using the combined nitrous oxide and ether method in practically all the cases operated on at Dr. Kelly's private hospital. The cases number between two hundred and three hundred. The method possesses so many advantages to the patient, operator, and anæsthetist, and so few disadvantages, that it has become an indispensable part of the operative technique of the writers.

The Lancet, October 27, 1900.

A Case of Separation of the Epiphyseal Head of the Femur.—By J. J. Clarke. The patient, a girl aged fifteen years, had fallen and was unable to stand. On entrance to hospital no fracture or injury other than contusion was made out, and she was ordered rest and liniment. Five months later she was seen by the writer, who found her very lame. Stepping on the right foot was painful, and the right limb was markedly averted. The right great trochanter was displaced upward and approximated to the anterior superior spine. The limb was an inch shorter than its fellow, and the gluteal fold on the affected side was shortened and curved up at its outer end. On the front of the right hip joint there was a prominence which suggested an anterior dislocation of the head of the femur. Passive adduction of the affected limb was easily accomplished, but abduction and flexion were painful to the patient and were greatly limited in their range. There was no crepitus felt in carrying out these movements. A good radiograph was obtained which clearly showed a break in the neck of the femur. Excision of the head of the femur

was advised and done. The parts removed consisted of the head of the femur (which was entire), the inner end of the neck, and separate fragments of granular callus. The head had remained connected with the neck by two portions of the cervical ligament, one at its postero-inferior aspect and another at its antero-inferior aspect. The ligamentum teres also was intact. By these connections it had escaped necrosis, but there was no attempt at bony union, the callus having been formed entirely from the neck of the femur. The separation had taken place exactly in the plane of the epiphyseal cartilage, no trace of which remained. The fragment of the neck which was removed was somewhat sclerosed. Although the patient in the present case had no definite signs of rickets, there probably was some weakening of the bone from slight inflammatory (rachitic) changes in the juxta-epiphyseal tissue, predisposing the patient to the accident. The operation was in every way successful.

The Differential Diagnosis in General Practice of Plague and Typhoid Fever.—T. Colvin, who had experience with the recent cases of plague in Glasgow, notes as characteristics of the disease its sudden onset with buboes, rapid rise of temperature, dyspnœa out of all proportion to any physical signs revealed on examination, general pains in the chest, cough and expectoration which is scanty and streaked with bright red blood, nervous symptoms of the delirious type coming on early, and absence of skin rashes. The general aspect of the patients after a very brief illness is that of a later stage of typhoid. The Widal test in the plague is negative, and if sputa are present the characteristic bacilli can be found in large numbers. As to the site of bubonic enlargement the author states that the most common glands affected are those in the groin. In almost half of the cases the inguinal or femoral glands, or both, are alone enlarged. The next common situation is the axilla and in order of frequency the cervical, submaxillary, and parotid glands. Enlargement of the supratrochlear, iliac, and popliteal glands rarely occurs.

The Anæmia of Dyspepsia Consequent on Dirt-Eating.—A. J. P. Duprey does not believe that the anæmia observed in ankylostomiasis following dirt-eating is due to the abstraction of blood from the intestinal mucosa by the parasite, but ascribes it to malnutrition, due to insufficient and improper food. This causes dyspepsia, which in its turn leads to anæmia, for the parasites in this affection feed not on the blood but rather on the soluble products of digestion which otherwise would have been absorbed and gone to nourish the system. He believes therefore that it is a mistake to suppose that the dirt-eating habit produces its symptoms from the parasites. Anthelmintics are of benefit, but recovery after their use does not follow as quickly as it would if the parasites alone were the causative factor.

British Medical Journal, October 27, 1900.

The Signs and Symptoms of Bubonic, Pneumonic, and Septicæmic Plague.—James Cantlie states that the skin is now generally considered to be the "port of entry" of the plague bacillus. The average period of incubation of the bubonic plague is from three to five days. The onset is generally sudden. The patient complains of splitting headache, of great weakness and prostration, of pains in the limbs and back, and sometimes in some one of the larger groups of lymphatic glands. In severe cases there are generally rigors or chilly feelings and often vomiting and nausea. Diarrhœa is not uncommon. The pulse is usually fairly full at first and of increased frequency. Respiration is rapid, and the temperature during the first three days may gradually reach 104 or 105 F., or even higher. Mental aberration appears early. It is as a rule the third day before the bubo appears. Abrasions of the skin should be sought for. Adenitis occurs in all varieties of plague except in the pneumonic and fulminant. In bubonic plague unilateral swelling of a group of glands is the rule, and one gland of the group proceeds to bubo. Various parts of the alimentary canal are affected. Constipation is the rule. The liver may be tender and somewhat enlarged: the spleen is invariably swollen. The urine is usually slightly albuminous. Sleeplessness is one of the most distressing symptoms in plague. In pneumonic plague the sputum is profuse, of a watery character at first. Generally blood does not appear till after twenty-four hours' duration of the illness. Pneumonic patches occur in either lung and at any portion. The severity of the onset of septicæmic plague is such that the patient resembles one attacked by active poison. Prostration from the first is extreme. Hemorrhages from the nose, bowel, or kidney are more frequent in this variety than in any other type of the disease. Apyrexia is not uncommon. Busy delirium followed by coma usually ends in death on the second or third day.

A Note on the Method of Using Haffkine's Prophylactic.—Margaret M. T. Christie in Calcutta in 1898, together with Dr. Nield Cook, inoculated some 2,490 patients between April and July, none of whom died of plague during that year's epidemic. The ordinary dose of Haffkine's prophylactic for an adult male was 5 c.c.; for a woman, 40 c.c.; for girls between the ages of ten and fourteen years, 3 c.c.; for children from two to ten years, from 1½ to 3 c.c. The writers selected the back and outer side of the arm midway between shoulder and elbow as the site of inoculation. The reaction in many cases began at once with pricking at this site, and the gradual formation of a hard, tender red swelling for a few inches round. The temperature rose within six hours. The height of the fever varied greatly, rarely lasting more than two days, though the arm remained more or less painful and tender for a week or ten days, and a small, hard nodule often remained for a few weeks. There were no untoward results.

The Bacteriology of Plague (with Illustrations on Special Plate).—David C. Rees declares that the micro-organism which he describes in detail in his paper is now the undisputed causative agent of plague. This organism resembles somewhat closely the bacillus of chicken cholera. It is generally from 1 μ to 2 μ in length and from 0.3 μ to 0.5 μ in width. It has rounded ends and is generally non-motile, although at a temperature of 37° C. it is actively motile. It does not form spores and has no true capsule. It is a facultative anaerobe. This bacillus is constantly present in the body of an individual suffering from the disease. If a susceptible animal be inoculated with material from this individual, the animal dies and the organism is found in its organs. These bacilli in their turn will prove fatal to other susceptible animals. The plague bacillus does not produce pus, but it can cause necrosis of tissue. If buboes containing the bacillus suppurate, it is generally due to staphylococcic and streptococcic infection.

A Case of Plague from a Clinical and Pathological Point of View.—William G. Savage and D. A. Fitzgerald sum up the chief points of interest in this case: (1) The enlarged glands; the absence of pain, tenderness, or inflammatory signs in or around the enlarged glands; (2) the bacilli in the blood were numerous enough to be readily detected microscopically; they were almost certainly bacillus pestis; (3) there were many whitish areas scattered through the liver which were probably necrotic; (4) the so-called carbuncles, red and subsequently necrotic patches on the shins, appear to be one of the characteristic features of plague, and were present on the first examination of this patient.

Cancers of the Heart.—Deguy states that these neoplasms comprise two distinct groups: primary and secondary. The first class consists of myxomata, sarcomata, and fibrosarcomata. Banti as well as Albers has observed a case of primary lipoma. The class of secondary neoplasms is more numerous. This group presents two very different types, sarcomatous and epithelial, the former possibly the more frequent. Wagner had already reported one of these cases; then Friedreich made the observation that melanosarcomata, remarkable for their malignity and their tendency to dissemination, seem to give rise most frequently to multiple metastases in the cardiac tissue. Nodules, some dark brown in color and others scarcely tinted, could be seen scattered through the cardiac tissue. The writer cites two cases which have come under his personal observation. The first was that of a man thirty-six years old, who was suffering from an ulcerating melanotic sarcoma on the right shoulder. At autopsy two nodules were discovered in the heart, one anterior, the other posterior; secondary nodules were found in the endocardium as well

as beneath it. The myocardium was filled with them. The second case was that of a woman sixty years of age, afflicted by an inoperable melanotic tumor on the right leg. Metastases were also found in this heart at autopsy. The secondary cancer may be either diffuse or nodular. It is a very important fact that in this affection the valves are usually spared. The semeiology will naturally be extremely varied; there are generally present, however, palpitations, pain, dyspnœa, arrhythmia, signs of pericardial effusion, and finally sudden death. It can be seen from this enumeration of symptoms that they do not form a characteristic group. The age of the patient and the existence of a neoplasm elsewhere in the body must also be taken into consideration.—*Gazette des Hôpitaux*, October 13, 1900.

Parasites of Cancer.—The announcement is made by M. Bra that in a series of cases of cancer he has found and isolated in pure culture from the blood and pathological tissues an organism belonging to the class of the lower fungi, and whose isolation is practically possible in the majority of cases. He has determined the morphological and biological characteristics of the organism. The inoculation and ingestion of cultures of this fungus reproduce in animals the anatomical lesions that are considered characteristic of cancer; these experimental tumors have the structure of sarcoma, of chondroma, and of carcinoma. The soluble products of the fungus have a vaccinal power which it would be possible to utilize after surgical operations to prevent recurrences. They exercise an attenuating influence on the pain, the hemorrhage, and the suppuration of cancer, and in some cases a curative action.—*La Médecine Moderne*, October 17, 1900.

Two Cases of Extreme Brevity of Vaccinal Immunity.—Charles Viannay cites these cases, which occurred in his own family, one five months after a successful vaccination, the other seven months. The disease was contracted by both individuals as they were nursing the writer, who was suffering from an insignificant attack of varioloid. The writer had been previously vaccinated six times without success, and then contracted the disease by making an autopsy on a virulent case. One of the first symptoms of invasion in the cases noted was aching of the legs which preceded the backache. During convalescence, the least fatigue caused a sensation of extreme lassitude in the legs. The history of these three cases would seem to indicate a family susceptibility to this disease.—*Lyon Médical*, October 14, 1900.

Hæmatemesis in the Course of Intestinal Occlusion.—From the study which Louis Tixier and Charles Viannay have given this subject, they believe that hæmatemesis in the course of intestinal occlusion offers a very grave prognosis just as gastric hemorrhage does in appendicitis. This complication is an indication of serious trouble dependent on the cause of the occlusion in the vasomotor innervation of the digestive tract and at the same time in the profound intoxication of the organism.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, September 23, 1900.

The Treatment of Metrorrhagia by Faradization.—Philippot believes faradization to be the best method of treating metrorrhagia. Its field of action is more extended than that of galvanization. It arrests positively the bloody discharge after a few applications which follow each other closely. Its employment is far more simple. It does not expose the patient to the unpleasant consequences to be feared from the other method. It is painless and causes most of the subjective phenomena to disappear rapidly.—*Le Nord Médical*, October 15, 1900.

Osteomalacia.—Adenot reviews an interesting case of this disease, and concludes that the infections have a very important influence on the development and evolution of osteomalacia; that castration probably does not act directly nor reflexly on the disease, but simply by preventing pregnancy, which favors the development of the osseous malady as it influences all other pathological states.—*Gazette Hebdomadaire*, October 14, 1900.

Berliner klinische Wochenschrift, October 8, 1900.

The Anatomy of the Accessory Nasal Sinuses.—G. Brühl describes a new method of demonstrating the exact position of the sinuses and their relation to surrounding structures. The heads are immersed in an acid solution of formalin, then treated with alcohol and ether, and finally with carbolized xylol. The cavities are filled with a molten mixture of lead, tin, bismuth, and cadmium called Wood's metal, which soon hardens. They are finally submitted to the *x*-ray process, which brings out a dark spot wherever the metal has penetrated. The positions of the sinuses are definitely located in the radiograph.

The Treatment of Bronchial Affections by Position.—O. Jacobson advocates the use of the prone position in clearing the bronchi of their secretions. The patient should lie flat on the stomach while the foot of the bed is raised. The method is practically of benefit only in chronic cases in which the muscles of the air tubes have lost more or less of their normal tone.

Cure of a Case of Epileptic Idiocy.—Edmund Rose describes the operative cure of epileptiform convulsions accompanied by aphasia and imbecility in an otherwise healthy boy after a comparatively slight trauma which produced a wound of the forehead above the left eyebrow. Shortly after this had healed the convulsive seizures began and continued for several months, while the patient lapsed into a condition of complete imbecility, with involuntary defecation and micturition, etc. In spite of the not very great hope of success from surgical interference, inasmuch as the uncontrollable outbursts of fury to which the boy was subject made permanent confinement in an asylum seem the only alternative, operation was decided on. Two trephine openings were made, one at either end of the scar, and the intervening bridge of bone was removed. No evidences of fracture or abnormalities of dura or brain substance were found even on exploring with the needle, and the wound was closed. Several months later it was learned that the attacks had steadily decreased in frequency until two and a half months after the operation they had stopped entirely, and that the patient's general condition mentally and physically was perfectly normal for a child of his age. Apparently the only explanation of this happy result lies in the supposition that the disease had been due to increased tension within the skull, and that the fact that one of the trephine openings was left unclosed and was occasionally bulged out by the pressure within furnished a safety-valve for this heightened tension.

The Pathology and Therapy of Vesical Tuberculosis.—Leopold Casper divides the treatment of this condition into the general hygienic, the local, the operative, and combinations of these three. The fact that the bladder lesion is frequently accompanied by involvement of other organs, or at least that the danger of extension of the disease is always great, makes the general tonic and strengthening treatment of the highest importance, and endeavors to increase the resisting-power of the organism should never be neglected. Of the drugs for internal use creosote and guaiacol carbonate appear to give the best results, though positive conclusions are hard to draw. Urotropin unfortunately is of no use in this class of urinary disease. In the opinion of many writers local treatment is contraindicated in tuberculosis of the bladder, and reliance should be placed solely on narcotics to control the pain. The author believes, however, that by careful irrigations, which should always be small in amount and never carried to the point of effecting the least distention of the bladder wall, much good may be done and even in isolated cases cures effected. Lactic acid (up to twenty per cent.) and bichloride solutions (1 : 10,000 to 1 : 1,000) give the best results, though the former is so unendurably painful in its application and after-effects that it can but rarely be used. Even the irrigation with bichloride solutions produces a painful reaction, but this is soon succeeded by diminution or cessation of the pain and improvement in frequency of micturition. Operative treatment does not promise very favorably, and should be resorted to only when there is a strong probability that the disease is strictly localized to small areas.

The Etiological Significance of Trauma.—Dirska deprecates the tendency to attach undue importance to acute trauma as a cause for secondary illness, especially in cases in which suits for damages are involved. Traumatic neuroses are often diagnosticated, but in the author's opinion are really comparative rarities. The possibility of the lighting-up of otherwise latent tuberculous pneumonic or cancerous growths through somatic concussions is, to say the least, problematic. There are three fallacies that frequently stand sponsors for an erroneous diagnosis of a traumatic origin of a disease. First, the assumption that it is particularly the lighter forms of injury that are followed by such consequences; second, one is easily carried away by the plausibility of an ingenious theory apparently correlating the supposed cause with the effect; and third, the factor of auto suggestion is strong in the patient and there is an almost universal tendency to connect illness with some previous injury.

Viscin and its Therapeutic Application.—G. Riehl gives this name to a substance obtained from viscum album, a

European member of the tropical family of the Loranthraceæ, which has long been used in the preparation of birdlime. It is the only European plant adapted to furnish a substitute for the expensive rubber and caoutchouc preparations so extensively used in medicine, and the author's attempts to elaborate a useful preparation have apparently been successful. The new agent is cheap, is readily prepared from the crude plant by simple processes, and is soluble in unirritating media. The combination most likely to be of general use in the treatment of dermatological and allied affections is a solution in benzin with which starch, zinc oxide, and salicylic acid, etc., may easily be incorporated, and efficient and cleanly substitutes for plasters and ointments secured.

Atrophy and Development.—M. Mühlmann divides cellular atrophy into three types, plastic, histogenetic, and necrotic. These are constantly influencing development and go hand-in-hand with growth. The earlier periods of development are dominated by the plastic and histogenetic forms of atrophy, although these are also to some extent present all through life, while it is necrotic atrophy that is most active in later periods and finally causes the death of the organism.

Münchener medicinische Wochenschrift, October 16, 1900.

The First Beginnings of Idiopathic Enlargement of the Heart, and the Significance of Dilatative Cardiac Muscular Weakness in Military Service.—Eugen Wolfhügel's observations, while conducted entirely on military material and being primarily of interest to army examiners and surgeons, have yet a practical bearing on the understanding of heart lesions in general. The usual belief that the acute and apparently wholly evanescent dilatation sometimes following sudden and severe exertion is a purely temporary condition without significance, and likely to occur to individuals in perfect health, is somewhat deprecated by the author, who is of the opinion that such an event is possible only in those whose muscle has previously been weak either naturally or as the result of disease, faulty hygiene, etc. Obesity, influenza, rheumatism, and, to a less degree than generally supposed, excessive beer consumption are factors predisposing to the weakness, while of the mechanical moments involved impeded respiration and increased blood pressure are of importance. The conditions under which the soldier does his severest work, viz., wearing a tight belt supporting heavy cartridge boxes, carrying a large and cumbersome pack on his shoulders, and encased in a snug uniform which restricts motion and does not permit active skin action, are such as greatly to diminish the vital capacity of the lungs, and in reducing the extent of intrathoracic changes of pressure to deprive the overburdened heart of a great aid in maintaining both the pulmonary and systemic circulations. Increased tension within the ventricles must be relieved in one of three ways—either by discharge into the arteries, dilatation of the ventricular wall, or incompetence of the auriculo-ventricular valve. If the first of these be difficult owing to high arterial pressure, dilatation may result, though in many instances the valves yield to some extent, and by a relative incompetence save the heart muscle. The author recognizes two forms of functional incompetence—first, this regulatory incompetence, which he likens to a safety-valve action, and second, the relative insufficiency following and due to dilatation. An attack of temporary dilatation sufficiently marked to give symptoms severe enough to call the patient's attention to it and lead to its recognition by a physician must have been preceded by other slighter, unnoticed ones; and while such attacks in a raw recruit are not necessarily serious, since by proper gymnastics the cardiac tone may be sufficiently improved to make their recurrence improbable, in soldiers of several years' standing they indicate disabling weakness and should lead to the man's discharge.

Cystitis Typhosa.—Hans Curschmann collates the statistics of numerous observers and finds that in at least fifteen to thirty per cent. of all typhoid cases the specific organism occurs in the urine. In view of the vulnerability of the parenchymatous organs, bones, periosteum, subcutaneous tissue, etc., to the pus-producing powers of the typhoid bacillus, it is rather remarkable that this very frequent bacteriuria is not oftener accompanied by cystitis. Published reports of such cases are rare, however, and considerable interest attaches to three such described by the author. In each of these the bladder symptoms were preceded by an albuminuria of low grade apparently purely febrile in nature which did not appear until convalescence was well under way. Typhoid bacilli were obtained in pure cultures from the purulent sediment in the urine, which was acid in reaction, this seeming to be a characteristic of the disease. But few subjective disturbances were noted; only one of the patients suffered from vesical pain and evinced a slight tendency to tenesmus. A temperature rise referable to the complication was not observed. The etiology of the affection is still obscure; there seems to be no satisfactory reason why the vesical mucosa that ordinarily is not attacked by the bacillus should in others be unable to resist it. The prognosis is favorable, for though the condition is prone to persist for some time, the symptoms are never severe and respond well to the usual remedies, among which urotropin is said to hold first place for this class of cases.

An Addition to the Technique of Leg Amputations.—E. Meusel, in order to prevent pressure gangrene of the flap over the sharp edge of the sawn tibia, has long used the following plan with great success: After the flap has been sutured it hangs down perpendicularly over the sharp and easily palpable tibial edge. A thread is passed transversely one and a half inches through the skin, three-quarters of an inch above the sawn end of the bone, and again similarly through the skin of the flap, three-quarters of an inch below the sharp edge. If the thread be now tightened and the ends tied the flap will be drawn straight up and a crease be formed over the dangerous spot, preventing all pressure gangrene. At the end of eight days the thread should be removed lest it cut in too deeply, but by that time the tissues will have gained sufficient vitality to obviate all risk.

Renal Hemorrhage in Hæmophilia Cured with Gelatin.—E. Hahn's patient was an hereditary hæmophiliac who for several weeks had been losing large quantities of blood daily from the kidneys with the usual consequences of protracted hemorrhage. Other forms of treatment having proved unavailing he was given large amounts of gelatin incorporated with his usual food, six to eight ounces daily being used. A marked improvement was noted on the next day and a permanent cure effected in a week. In view of the simplicity and harmlessness of the procedure, together with the fact that it does not interfere with other modes of treatment that may be carried on simultaneously, it seems well worth trying in such cases.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE ELECTION—ACTINOMYCOSIS—GASTROTOMY FOR HÆMATEMESIS—EARLY TREATMENT OF ABDOMINAL SYMPTOMS—SUBCUTANEOUS SYMPHYSEOTOMY—NATIONAL HOSPITAL SCANDAL—GUILD OF ST. LUKE—LONDON UNIVERSITY—TYPHOID—DEATH OF SIR H. ACLAND.

LONDON, October 19, 1900.

THE general election is over and the excitement connected with it is rapidly subsiding. There are eleven members of the profession in the new House. All were in the last except one—Rutherford Harris, known in connection with the South African Company rather than as a doctor. Some of the others have forsaken medicine for other occupations. Three doctors lost their seats. The strength of the profession in the House will be about the same as before.

A case of actinomycosis related by Sir D. Duckworth gave rise to a little discussion at the meeting of the Clinical Society. It was a case in which subdiaphragmatic abscess ensued. Mr. Marsh remarked on the difficulty of diagnosis and thought operative interference would in such cases be useless. Mr. Godlee took a more hopeful view, as many patients suffering from actinomycosis of the cæcum, abdominal wall, face, and neck recovered after scraping and a course of iodide of potassium. This view was supported by other speakers. It was also mentioned that the fungus is destroyed by carbolic acid, and a case was mentioned which ended in recovery after scraping followed by the application of this acid.

Mr. Mansell Moullin then read notes of three cases of gastrotomy for hæmatemesis. In two the source of bleeding was superficial erosion of the mucous membrane, which he strangulated with silk ligatures at the base. In the

other the ulcer was too large and the base too soft for this plan, so a stout ligature was tied tightly round the part of the stomach wall on which the ulcer was situated, and union of the serous coat secured by some Lembert sutures passed from the peritoneal surface. There was some fresh hemorrhage a fortnight afterward, possibly from separation of the ligature, but the patient quite recovered and is now well. Mr. Moullin said that although hæmatemesis is said to be fatal in only four or five per cent. of cases in which ulcer of the stomach is diagnosed, it often places life in danger and more often causes so much apprehension that if this operation prove to be unattended by great risk many sufferers would prefer the chance of perfect cure to months or years of semi-starvation, and the possibility of sudden death always before them. The stomach, owing to the thickness of its coats, bears sutures better than the rest of the digestive tract, and there is no reason why the mortality should be greater than in appendix cases, provided the operation is performed early and not when the patient is *in extremis*. The difficulty of finding the bleeding spot is great, and Mr. Moullin mentioned a case in which death had occurred after abdominal exploration. If such a case occurred to him again, he would reopen the abdomen and search, and would, if necessary, incise the stomach wall to find the bleeding spot. In one of his cases the erosion would in all probability have been overlooked at a post-mortem, but the bleeding still going on when he operated revealed the spot.

The early treatment of abdominal symptoms was the subject of Dr. Schacht's inaugural address at the West London Society, and he raised a voice against too precipitate a recourse to operations. Recognizing the triumphs of surgery he also recalled that many fashions had arisen and passed away in regard to abdominal surgery. The surgeons' familiarity with the peritoneum taught them to differentiate many cases, but the clinical symptoms were much the same as of old. Those most frequently present —vomiting, constipation, diarrhœa, increased temperature and pulse, pain, tenderness—were most valuable in some cases, but individually were uncertain and very often were absent. He therefore thought that all cases of doubtful abdominal symptoms should be treated at the earliest stage in one manner, viz., absolute rest in bed, restricted fluid diet, avoidance of all aperients, and small doses of opiates, preferably as hypodermic injections of morphine.

The frequent reiteration of "wasted early opportunities" in reading had so struck him that he felt our increased knowledge had perhaps developed a new danger, viz., a liability to overlook medical prevention on account of our familiarity with surgical cases. Prompt treatment in the earliest stage would shorten many an illness, lessen its gravity, and diminish the necessity for surgical interference.

Subcutaneous symphyseotomy was the subject of a paper read at the Obstetrical Society by Dr. Herman. He pointed out the advantages of the procedure in its simplicity, quickness, small risk of sepsis, and insignificant hemorrhage, and then argued that to obtain the most favorable conditions it should not be delayed until the failure of the natural powers made some operation immediately necessary. The accoucheur should ascertain the size of the pelvis before labor and estimate the size of the child. If he decided on symphyseotomy, the most favorable time for it was immediately after full dilatation of the os. The chief risk of the operation was injury to the urethra, and this was most likely to occur when the child was too large. Careful estimation of the size beforehand was therefore the only means of guarding against it. Dr. Griffith described an easy mode of ascertaining the relative size of the head and pelvis. The patient sat on the edge of the bed at such an angle that the long axis of the fœtus was vertical. Its head, then, if smaller than the pelvis, would dip into the cavity owing to gravity. Dr. Lewers had in one case found a dovetail in the middle of the joint, and had to use a saw. Dr. Spencer thought the subcutaneous method had advantages, but it must be remembered that severe hemorrhage from division of large vessels had been recorded. If the vagina was wounded, there was also some danger of sepsis. Dr. Herman in his reply said laceration of the vagina was not of importance unless it reached the urethra. He would try Dr. Griffith's plan of estimating the size of the child's head and pelvis.

The board of the National Hospital for Epilepsy and Paralysis has resolved that an inquiry is desirable into the charges that have been made, but in the letter to *The Times* stating this there is no allusion to the claims of the staff. The board seem unconscious that the accused is not the person to appoint a judge. But this board, or its "secretary-director," will no doubt proceed to ask some one to conduct an inquiry. It is not likely the staff will accept such a course.

The service at St. Paul's Cathedral under the auspices of the Guild of St. Luke was held on Wednesday evening. About one hundred and fifty doctors attended, and a goodly proportion wore their robes, to the delight of the promoters of the Guild, who attach great importance to such an exhibition of collegiate clothes, and appeared arrayed in all the glory of their various gowns and hoods. The Bishop of Rochester preached the sermon.

The reorganized London University will soon be at work. The chancellor, senate, and convocation have been elected. The standing committees and other boards will no doubt soon be appointed, and this complex institution will show what it can do.

Typhoid is increasing, as I intimated it was likely to do. There were seventy-one more cases admitted in the week, bringing the number in the hospitals to four hundred and five. The deaths were proportionately increased to twenty-two from the fifteen of the previous week. Scarlet fever showed an increase of above one hundred cases, but the number of deaths fell from fourteen to seven.

Sir Henry Acland, Bart., K.C.B., F.R.S., died on Tuesday evening. He was born in 1815, educated at Oxford, in 1841 became a fellow of All Souls', took his M.D. Oxon. in 1848, was elected F.R.C.P. Lond. in 1850. Subsequently he became professor of medicine at the University of Oxford (1858 to 1895), and a recognized, highly esteemed leader of the profession. You will remember that he accompanied the Prince of Wales on his trip to America (1860), and since then has been one of His Royal Highness's physicians. Cambridge, Edinburgh, and Dublin conferred on him honorary degrees, and a number of American and continental medical societies enrolled him as member. Among the numerous offices he had held were the presidency of the General Medical Council, the curatorship of the Oxford University galleries, and of the Bodleian Library. He also served on several commissions connected with education and sanitation. He wrote memoirs of Sir B. Brodie and of Dr. Stokes, and numerous contributions to medical and sanitary science. The fine work on the "Oxford Museum" was jointly by him and Ruskin—his intimate friend.

SUBARACHNOID COCAINE ANÆSTHESIA.

To the Editor of the Medical Record.

Sir: I believe in giving credit to whom credit is due. When we give a historical *résumé* of the origin and development of subarachnoid anæsthesia, Dr. J. Leonard Corning's name should occupy a conspicuous place. He was certainly one of the first to perceive the "possibilities" of the method of spinal cocainization. But it seems to me going a little too far when an attempt is made to parade Dr. Corning as the sole originator, discoverer, and introducer of the method, and we certainly lay ourselves open to the charge of ultrapatriotism when we designate it as "Corning's method." Dr. Corning—and I say this notwithstanding the high esteem in which I hold the doctor and his contributions to neurology—had only a dim perception of the possibilities of the method. He stated distinctly that it was not necessary to penetrate the subarachnoid space, while, as we know now, the method is absolutely worthless unless the needle has penetrated the spinal column and cerebrospinal fluid has been seen to exude. Again, he had not used his method in a single operation (the passage of a sound cannot be considered one), and was himself uncertain whether the method would ever find an application in genito-urinary or other branches of surgery. It is the method of *sub*arachnoid anæsthesia that promises to work a revolution in general surgery and obstetrics, and the credit for that method undoubtedly belongs to two men—to Prof. August Bier and to Professor Tuffier: to the first as the discoverer of the method, to the second as its popularizer. Very respectfully,

William J. Robinson, M.D.

119 East One Hundred and Twenty-eighth Street,
New York City.

Rectal Fistula.—The various methods which have been employed from the earliest time may be classified as follows: 1. Methods designed to promote healing without laying open the fistulous tracts, these are: (*a*) Cauterization; (*b*) compression; (*c*) subcutaneous division of the sphincter ani externus; (*d*) curettage with packing of the fistulous tract. 2. Division of the tissues between the fistula and the rectum is accomplished: of these we have: (*a*) Simple incision; (*b*) ligature; (*c*) écrasement; (*d*) galvano-cautery.—Dr. A. E. Halstead, *Illinois Medical Journal*, October.

Society Reports.

THE PRACTITIONERS' SOCIETY.

One Hundred and Fifty-seventh Regular Meeting, Held on Friday, October 12, 1900.

A. Alexander Smith, M.D., President, in the Chair.

A Case of Vertigo of Doubtful Origin.—This case was presented by Dr. H. M. Biggs. The patient was a man, forty-seven years old, a Canadian; his occupation was that of a farmer, and in former years he followed the sea. His family history was negative. He had gonorrhœa about twenty years ago. He denied syphilis, and was well up to two years ago, when he had an attack of influenza, and to this he ascribed his present illness. Subsequent to this attack he first noticed a tendency to sway and some vertigo. This symptom had gradually increased in severity, and when Dr. Biggs first saw the patient, about a month ago, the vertigo was so pronounced that he could with difficulty maintain his equilibrium in walking, and he was sometimes unable to walk without assistance. When he lay down his vertigo disappeared, but it reappeared at once when he got up and tried to walk. Aside from the vertigo, the man's only symptom was a severe headache, partly frontal and partly occipital. He had not suffered from nausea or vomiting until about two months ago, and then he attributed his gastric disturbance to some strong medicine he was taking at the time. There was also at that time some loss of appetite, but these symptoms had since disappeared. The motor and sensory functions appeared to be normal. There was no marked change in the arteries. His vertigo was slightly better in cold weather. In staggering, he usually fell to the right side, but sometimes to the left. The patient's eyes were examined by Dr. Peter A. Callan, who found a slight degree of astigmatism, which was corrected by glasses. Since then the patient stated that he had been free from headaches. There were no symptoms, ocular or otherwise, which indicated cerebellar trouble. There were no symptoms pointing to labyrinthine trouble. The patient had never experienced sunstroke. Dr. Biggs said he put the patient upon small doses of potassium iodide and inunctions of mercury. The former soon gave rise to severe gastric symptoms. The mercurial inunctions were continued until the physiological effects of the drug were apparent. Following this there was a decided improvement in the man's symptoms.

Dr. Charles Stedman Bull said that symptoms like those described in this case were not at all uncommon after the occurrence of grippe, and they often persisted for a long time, even without a discoverable lesion. One explanation that had been offered was that they were due to a hemorrhage in the labyrinth; another, that there was a serous inflammation of the lining membrane of the labyrinth. In such cases there were absolutely no objective symptoms. In the early stages they were difficult to differentiate from cerebellar disease of a malignant type, and in order to distinguish one from the other developments must be awaited. In the case shown by Dr. Biggs cerebellar disease could be excluded, as the symptoms had lasted for nearly two years and there was no hemianopsia. As regarded treatment, Dr. Bull suggested the use of pilocarpine hypodermically. The dangers of this drug should not be lost sight of.

The president, Dr. Smith, said he had seen two similar cases in which the symptoms were relieved, one by pilocarpine, the other by the fluid extract of jaborandi.

Dr. Walter B. James suggested that the hot-air cabinet might answer the same purpose and be safer.

Dr. Robert Abbe said the labyrinthine theory would not explain the frontal and occipital headaches. He had been struck by the similarity of the symptoms in this case to those of cerebellar tumor. In the latter case, however, hemianopsia would be present.

Dr. Smith said that in one of his two cases headache was quite a pronounced symptom.

Dr. J. W. Brannan called attention to the fact that the reflexes were quite markedly exaggerated in Dr. Biggs' case.

Dr. Bull said the reflexes were not influenced in labyrinthine disease.

Some Clinical Aspects of Gout.—This paper was read by Dr. Beverley Robinson (see page 721).

Dr. George F. Shrady said that Dr. Robinson's paper opened a wide range for discussion. The remarks on appendicitis seemed to be a challenge for the surgeons to discuss that particular aspect of the subject from an entirely different standpoint than that presented by Dr. Robinson. Personally, Dr. Shrady said, he had never seen a case of rheumatic appendicitis. The theory of a possible relationship between gout and appendicitis was a very taking one, but at the same time a very dangerous one, because in obscure cases it might lead one to temporize and lose valuable time. Of course, it was well known that there were cases of appendicitis in which recovery took place without the knife, but the very large majority of them imperatively required operation. It was proper for the physician to have his say against the surgeon, but statistics proved the utility of operative interference as the almost inflexible rule, and the condition could hardly be discussed on a purely gouty basis.

Dr. Dana said that he considered gout a form of defective metabolism which the individual inherited or acquired, and that the nervous system controlled in a measure its acute exacerbations; otherwise he did not think gout had much to do with the nervous system or with nervous diseases, except secondarily through the arterial changes. It was not often a factor in causing the organic or functional diseases seen by the neurologists, and he rarely had occasion to prescribe colchicum or the other gout specifics. There were, he thought, four forms of defective metabolism which were met with by the physician, all having a certain kinship; these were rheumatism, lithæmia, gout, and rheumatic gout. One of these four processes, that known generally as lithæmia, was in particularly close relationship with the neuroses. It was a disorder of metabolism which stood apparently between rheumatism on the one hand and glycosuria on the other; it was not entirely identical with rheumatism, nor was it at all identical with gout, and it had, he thought, a certain independence in its pathology. It did not respond to the salicylates or to colchicum in any such way as acute rheumatism or gout itself, and it was certainly not due to an excess of uric acid, because very often there was no such excess in these patients.

Dr. Robert Abbe said he thought it important that surgeons should combat the theory that peritonitis of gouty or idiopathic origin was a factor in the ordinary run of cases which they were called upon to treat. The speaker said he had never seen a case of gouty peritonitis, and experience showed that peritonitis was invariably bacterial in origin, and that it was due to the transudation of the bacteria or their toxins through the walls of the intestines. If many cases of peritonitis which were usually attributed to appendicular trouble were really of gouty origin, how would Dr. Robinson explain the fact that the inflammation was invariably on the right side? Dr. Abbe said that in several hundred cases of recurrent appendicitis upon

which he had operated between the attacks, the gross appearance of the appendix in perhaps thirty or forty per cent. was apparently normal, but after distending and hardening them in alcohol, and slicing them lengthwise it was easy to make out the sequelæ of a chronic catarrhal inflammation with strictures. They all showed hypertrophic changes in the mucosa and muscular coats, with resulting strictures. With each repeated acute attack there were putrefactive changes within, and when the stricture finally became complete, rupture and septic peritonitis occurred. These gradual changes in the appendix might extend over a period of from five to twenty years, and such patients usually gave a history of recurrent attacks of appendicitis, which were apparently cured by all sorts of medicinal remedies, but finally an operation became necessary, or grave consequences ensued. Dr. Abbe said he considered the term "catarrhal appendicitis" a legitimate one, yet to speak of each attack as catarrhal was not legitimate, because the primary catarrhal condition dated far back, being perhaps a sequel of general influenza, of typhoid fever, or of some intestinal trouble which left a lurking focus and led to the subsequent symptoms. To say that there was originally a gouty element in the condition was open to grave doubt.

Dr. Joseph D. Bryant said that in several cases of gout which had been under his close observation for many years, a nitrogenous diet had proven very satisfactory. He said he was not disposed to take Dr. Robinson's statements regarding a possible relationship between gout and appendicitis very seriously. If such a relationship could be demonstrated by the author of the paper in any given case of chronic appendicitis, the speaker said he would be willing to submit the patient to a thorough course of treatment for the relief of the gout before advising surgical interference, provided Dr. Robinson would assume the responsibility of the delay. It had been found at autopsy that in at least sixty per cent. of persons who had died from various causes the appendix had undergone pathological changes: it would be very unfair to assume that in all those cases the changes depended on gout. In many cases the appendix had been found to contain fecal concretions and purulent products, which certainly could not be wisely ascribed to gout. Many patients recovered without operation and without any treatment directed to gout. Moreover, gout and appendicitis manifested their respective characteristics at periods of life so widely dissimilar as not to encourage belief in the existence of a specially causative relationship between them.

Dr. Andrew H. Smith said the problem brought up by Dr. Robinson could be solved by the collection of sufficient data bearing upon the subject. We could learn, for example, the proportion of cases of appendicitis in which there was a history of antecedent gout, or a gouty tendency. We might thus be able to arrive at some definite opinion as to whether the gouty infection was responsible for the original narrowing of the lumen of the appendix, and that this was followed, in the course of time, by the usual symptoms of appendicitis. There must be some beginning for these pathological conditions affecting the appendix, and it was known that only in a small proportion of cases had concretions or other foreign bodies been found in the appendix. What was the first departure from the normal condition of the appendix, and what caused it? After the pathological condition described by Dr. Abbe existed, all were, of course, willing to admit that surgical interference was necessary. The original cause of the condition, however, if it could be learned, might be prevented in a certain proportion of cases.

Dr. Robinson, in closing, said that Dr. Smith had struck the particular point which the speaker deemed essential in his remarks about appendicitis. He would be extremely loath to have any one believe that in his opinion appendicitis should not be operated on under certain conditions, nor did he mean to imply that all cases of appendicitis were of gouty origin. A certain number of cases, however, had come under his observation in which the gouty nature of the affection was very probable. Of course, in speaking of gout we should not confine ourselves to those cases in which there was a history of swollen joints and nodular deposits, such as any medical student would recognize at a glance, but we should also bear in mind the more obscure manifestations of the disease; these the speaker had in mind when he spoke of the possible relationship between gout and appendicitis. The philosophy of medicine taught us to try to learn the underlying factors of a disease. The mere fact that an operation was safe did not prove its utility.

THE NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, October 23, 1900.

John H. Huddleston, M.D., Chairman.

The City and its Consumptive Poor: A Plea for a Municipal Sanatorium Outside of the Corporate Limits.—Dr. Alfred Meyer read this paper. One year ago, he stated, he had addressed the section upon the subject of the State care of the consumptive poor, since which time there had been cause for rejoicing in that the State of New York was finally induced at the last session of the legislature to commit itself to the principle of State aid by the appropriation of $50,000 for a State sanatorium. Twenty-six sites in the Adirondacks had been inspected by the commission appointed by the governor, and but recently a decision had been made in favor of Clear Lake. In spite of delay caused by opposition he thought there was a strong probability that within the next eighteen months the State of New York would have reared its first sanatorium for the cure of incipient tuberculosis. The first organized effort in this city for a separate institution for the consumptive poor dated back to 1855, when a society, with Peter Cooper as president, and Dr. Alonzo Clark and other well-known citizens as trustees, was chartered by the State and issued "An Appeal to the Inhabitants of the City and State of New York." The arguments used were almost identical with the ones used to-day. Last year the object of his paper was to enlarge the State's responsibility for the indigent consumptive; in his present paper his object was to urge the need of greater responsibility on the part of the city. The main obstacle to action under the law for the establishment of hospitals for the regular treatment of pulmonary tuberculosis had been the bugaboo of expense. Dr. Meyer quoted from a recent article in the *Wiener klinische Rundschau*, written by the director of the sanatorium at Alland near Vienna: "The great expense connected therewith, which appears to be the main argument against the establishment of municipal sanatoria, must appear in an entirely different light to every one who studies the facts—that is, to every one who studies what it costs society to support the consumptive until he dies, and what it would have cost had he been cured or at least sufficiently improved by treatment according to modern methods to permit him to return to the ranks of bread-winners." Enormous sums of money were being spent to-day without the saving of a single life, merely because it was being spent at the wrong time. Our motto should be, as so forcibly expressed by Dr. Pryor, of Buffalo, last year:

At the right time, in the right place, in the right way, until cured; not at the wrong time, in the wrong place, and in the wrong way, until dead. How much would it cost the city, approximately, if it were to embark upon a project of this kind? According to the board-of-health reports there were in Greater New York during the current year, up to and including September 22d, 6,079 deaths from pulmonary tuberculosis, from which could be deduced a total number of deaths for the year 1900 of about 8,100. If we remembered that the death rate and the average duration of the disease remained about the same, we were forced to the conclusion that there were about 8,100 new incipient cases each year taking the place of those who had died. If each one of the 8,100 had six months' sanatorium treatment, the expense would be equivalent to the care of one-half that number for one year, or about 4,000 cases. At a very liberal estimate nine-tenths of these might be classified as poor and liable to become a public charge; this reduced the total to 3,645. If we allowed for those taken care of by private charitable agencies the number was further reduced to about 3,000, for whom buildings and equipments would cost about $3,000,000 and annual maintenance about $1,000,000. But no one had asked that this burden be assumed by the city. An appropriation of about $300,000 is all that the friends of this measure were asking for, and those who persisted in claiming that this sum was but the beginning of an endless chain of annual appropriation should recall the fact that in the future the city would be the judge of the practical value of its first investment. Dr. Meyer then tabulated a few cogent reasons why, in his opinion, the proposed hospital should be established: First: The problem was an enormous one and required the union of all forces, municipal, State, and private. Second: There was no doubt that the expressed sentiment of the profession in this city was in favor of the plan. Third: The increased hopefulness of the medical profession of the curability of the disease. The results in Germany had been so favorable and had stimulated the erection of sanatoria to such a degree that about twenty thousand incipient cases could now receive treatment for three months each, and seventy-two per cent. of these were returning to the ranks of wage-earners. Fourth: The inadequacy of public and private endeavor. Two conclusions drawn from figures quoted were, that the city was doing insignificantly little, and that private charity was doing twice as much. Fifth: The disease was a menace to public health. Sixth: An object-lesson would be given by New York to those other municipalities in the State to which the same authority had been given, as yet, however, barren of results. Seventh: There would be great value in the hygienic enducation of the patients, and their training in the proper disposition of their sputa would diminish the spread of the disease. Eighth: The money value to the city of lives saved would be millions of dollars, whether estimated by what it cost to rear and to educate an individual, by what it cost to care for dependent widows and children, or by the law once upon the statute books of this State valuing a life at $5,000. Ninth: At a general meeting of the Academy of Medicine held December 21, 1899, a resolution favoring the establishment of municipal sanatoria was indorsed.

Dr. John B. Cosby, commissioner of charities, pledged his support in all efforts made toward procuring such hospitals.

John W. Keller, commissioner of charities, in referring to the number of phthisis patients, the number of beds reserved for them, the number who died, etc., in the hospitals of the department of public charities for the borough of Manhattan and the Bronx, stated that an analysis of these figures would show that the demand for room for the treatment of phthisis patients was in excess of the supply. They also showed that of the patients admitted from January 1 to October 1, 1900, more than one-third had died. The boroughs of Manhattan and the Bronx had not enough room in their public hospitals to care for phthisis patients properly. Necessary isolation could not be had, although there was a prospect for an early and effective remedy for this deficiency. In February of next year the Manhattan State Hospital would have to leave Blackwell's Island, and the three buildings now occupied by the insane would revert to the department of public charities. Two of these buildings were isolated, and patients there need not come in contact with any other class of patients on the island. He, therefore, thought that the borough of Manhattan and the Bronx would have ample accommodation next year for all destitute persons suffering from phthisis. The figures demonstrated the fact that there were six hundred and thirty-five deaths among eighteen hundred and thirty-nine patients; he thought this was too great a death rate, but believed that, with the additional accommodations on Blackwell's Island, it would be materially reduced. He expressed himself as being heartily in accord with any movement for the relief of the destitute suffering from this dreadful disease.

Dr. Herman P. Biggs said that this was a matter in which he had been interested for years. Six or seven years ago he had urged upon the department of charities the necessity of adequate care for tuberculous patients, and had asked that the receiving-pavilion at Bellevue Hospital be set aside for these patients, and also that sanatoria be established for the care of incipient cases. He had then suggested that Central Islip might be a suitable place, since the city then had a large tract of land there. H. H. Porter was commissioner of charities, and had acquiesced in the plan proposed by Dr. Biggs. The plan fell through on account of lack of money enough to carry it out. At that time the question of the transfer of the insane to the State hospital had come up for consideration. As a result, a certain number of wards had been set aside in the City Hospital and in the Almshouse, and subsequently pavilions were erected at the Almshouse to be devoted to the care of these unfortunates. When the insane were removed from the Metropolitan Hospital these wards were assigned for the care of such cases. In the following administration, that of Mayor Strong, there was a scheme for the establishment of a reception pavilion at Bellevue: appropriations were made, and the erection was begun. That building was just ready for occupancy. He was strongly in favor of establishing sanatoria. So far as this city was concerned, he believed that the total number of cases, as estimated by Dr. Meyer, was far below the actual. He stated that the department of health was primarily interested in the prevention of the disease; that the care of incipient phthisis also came properly under the department's care, yet it was not so much the prevention, but the cure, for which the sanatoria were required. There were two sides to be considered so far as the department of health was concerned: first, what could be done in the way of saving lives, and, secondly, what could be done in the way of prevention. In 1889 Dr. J. D. Bryant had introduced a resolution asking for the report on the prevention of tuberculosis. Drs. Loomis, Prudden, and Biggs were the consulting pathologists, and they submitted a report. Many prominent physicians were consulted as to whether they considered it advisable that any action should be taken looking toward prevention; a negative reply was received from all but one—Dr. Janeway. All others were opposed to any action on the part of the department. Then it was decided that

it was not advisable to take any action except in a limited way—that is, in the way of education of the people. Many circulars had been given out. Nothing further had been done until 1893, when a resolution was entered calling for the report of all cases of tuberculosis, and physicians were requested to aid. Following this in 1894 the department commenced an inspection of all cases occurring in lodging-houses. In 1897 tuberculosis was declared to be a communicable disease. Since 1888 there had been a reduction in the death rate from tuberculosis in this city. In 1888 the death rate was 4.04; last year it was 2.87. He emphasized the fact that the function of the department of health was the prevention of the disease, by education of the people, by disinfection and renovation, etc. He was strongly in favor of establishing such institutions. The appropriation made in 1897 for the care of such cases in Seton Hospital was made at his suggestion.

John P. Faure, ex-commissioner of charities, was extremely glad to notice such agitation of this question. During his time of service in the department he naturally saw a great many cases, and it was a matter of much regret that he could not separate them. He was particularly glad that the department now saw a way clear to do so. Again, he thought it was a matter of great desirability that the department recognize the value of specialists or those with some special idea. It had been his privilege to be identified with work among sick children, the floating hospital of St. Johns Guild, and he believed that the large diminution in the death rate among children was due to the fact that somebody was doing something in a definite direction. He therefore favored this movement. He had recently attended a meeting of the Brotherhood of St. Andrew in Richmond, Va., where he had heard a voice from Denver. The chapter in Denver saw that many of these cases were relieved; also, that many of those coming there were poor and came too late, and the death rate was large; yet many recovered. The young men of this organization in such a small place as Denver got together and purchased land for a ranch in order to give the people who went there the benefit of climate at a minimum expense. It seemed to him that if the poor young men of Denver could voluntarily set to work to gain such an object and set such an example of what could be done, it should spur on those present to accomplish the object under discussion.

Rev. James M. Buckley, LL.D., president of the board of managers of the Methodist Episcopal Seney Hospital, Brooklyn, was convinced that both philanthropy and self-protection required the institution of measures to aid those of the poor who were yet in a condition to be helped, and to give to the families to which they belonged freedom from the danger of the close contact which was inseparable from urban poverty. He fully sympathized with the movement. The city of New York should avail itself of the provisions of the law and try one experiment thoroughly. The results would show whether it remained an experiment or furnished a demonstration.

Jacob H. Schiff, president of the Montefiore Home for Chronic Invalids, believed that tuberculosis could be efficiently dealt with only in sanatoria located in favorable surroundings, well removed from centres of population. Some few years ago a plot of one hundred and thirty-six acres was selected at Bedford Station, Westchester County, about forty miles from New York City, and provided accommodations for a limited number of phthisis patients, mostly those in the earlier stage of the disease, who had already been inmates, or, upon proper application, had been found to be proper subjects for admission to the benefits of the Montefiore Home. The number of these patients taken care of there was thirty, and so satisfactory were the results that the directors of the Montefiore Home, about eighteen months ago, came to the conclusion that they would erect larger buildings at Bedford Station and remove thereto all of the phthisical patients coming under the care of the Montefiore Home. The new buildings were destined to accommodate one hundred and fifty patients. He did not think private philanthropy could ever be able to deal adequately with the situation, and could, at best, only experiment for the benefits of the State, and, with the experience gained, point out the means which the State must employ if it was to do justice to its duty toward its people. He thought the time had arrived when proper steps should be taken by the commonwealth to deal in an efficient way with this problem, without leaving it any longer to private attempts alone.

Charles C. Savage, president of Roosevelt Hospital, said that forty years ago he had been a member of a convention of physicians which took up the question as to the contagiousness of yellow fever, and it had been decided that it was not contagious; there was no doubt that fomites, such as clothing, etc., could carry yellow fever away from the patient, and infect those who were liable to such infection. Another question brought up pertained to smallpox; there was but one opinion, which was that it was contagious. In reference to this last disease great progress had been made, especially in regard to vaccination. During the past fifty years he had had much experience as a layman in hospitals and dispensaries, and he had been greatly interested in the endeavors made to stamp out smallpox. Now he was confronted with tuberculosis, and he asked if it could be stamped out, and if it was contagious. He believed that it was infectious, and that it would be carried to those who were susceptible to it. He again asked what could be done to eradicate it. It must be stamped out in some way. In New York there were one million and a half people living in residences that contained two or more families. The hospitals could not care for these patients, because they had not the means, and besides he did not think it was right to place the patients there. He did not believe that they should be sent to the Adirondacks, because it would require too great an expense, because it was too far from their homes, and because of the difficulty in getting them there. He believed that it would be wiser to isolate them properly on Blackwell's Island and see what could be done there.

Assemblyman Nelson H. Henry said it was impossible to obtain a reason for the disapproval of the bill on the part of the mayor after the bill had passed the legislature last winter. He believed that the people in the State of New York had, to a certain extent, been educated up to the point of recognizing that something must be done toward treating tuberculosis cases, not only in human beings but also in animals, particularly the bovine species. The people must be educated, and particularly the representatives in the State must be educated in order that they may be won over and make the proper appropriation for the carrying on of such a purpose. It was not well to be discouraged at the failure last year of getting an appropriation of $250,000 or $500,000; nor at the failure of such a bill to pass the mayor last year. He thought that probably those present, including Dr. Cosby, had not been able to educate the mayor up to learning the importance of this matter. It was a most important point in dealing with these things not to use too drastic measures. He thought we were quite far off from the compulsory removal of tuberculosis cases from our midst. The people should recognize first the importance of such a law. If we started out with the posi-

tion that the cows were responsible for tuberculosis, and that they should be removed from our midst, we would immediately rouse the anger of the farmers throughout the State. We must be patient until the hayseeds died off, and await the advent of the modern farmer who might appreciate what was best for his interest and assist in stamping out tuberculosis. It was very hard to train the old hayseed farmer. The removal of the incipient cases was generally recognized as the one thing certain to secure the most beneficial results. He had always held the view that we should establish hospitals for the advanced cases near our dense centres; we could accomplish much in giving them a place of comfort, but we should also look beyond that and see what good would come to the locality whence they had been removed. He believed that the secret of successful treatment lay in the improvement of the general sanitary conditions among the people as well as among animals. The old-style barn should be cleared out, and hygienic stables erected, which supplied proper air and exercise for the cows, etc.; this would probably stamp out tuberculosis in New York. The same principle would apply to the poor of New York: the tenements must be improved. It was his experience that the legislators in Albany had given this subject much attention, that they were convinced that something should be done, and that it only rested with the people to push the matter; they should state just what was the best course, not ask too much, and they would get legislative support. He emphasized the fact that the people should be educated in this most important subject.

Dr. Cosby, referring to what Mr. Henry had stated about the mayor not signing the bill, said that the mayor's reason for not signing it was that he did not know where the expense of it would stop. If only $150,000 was called for he thought that amount could be obtained.

Dr. Henry W. Berg said it was the duty of the community to care for tuberculosis cases. There were certain cases the department of health could take care of, but the department was limited in this effort by the amount of money in hand. He asked if it was the duty of the department to take care of the incipient cases. He divided tuberculosis into two classes: first, very bad cases, or cases of chronic consumption which had reached the last stage; second, those cases which modern science had shown to be in the curative stage of the disease. Fortunately, incipient phthisis was curable, and as a civilized community it was our duty to treat the disease by the most successful method. The best method of doing this was the segregation of the cases in sanatoria, and the first requisite for entrance into these establishments was that the patient should have a certain amount of money. That requisite excluded from the benefit of these sanatoria a large number: those who had no money. He thought it was more logical to devote money to the cure of the disease than to the maintenance of these patients; they should not be allowed to become a source of danger to the community, but should be cared for in sanatoria. The treatment did not consist in the administration of drugs, serums, or antitoxins; the best method of treatment was the one advocated by Dr. Meyer.

J. J. McKelvey said it was a fact that nearly every public agitation was opposed on the ground that it led to the injury of persons or property, and he did not think this present agitation was an exception to the rule. Several years ago the State legislators began to take notice of these cases of tuberculosis among the poor of the city; they tried to find means for bettering the conditions of that class of consumptives; they naturally looked to the hospitals. The concentration of these patients in public hospitals could be effected by various charitable organizations or by the appropriation of a certain amount of money to be used for their care in these institutions. That would result in concentrating these patients in particular localities. Property interests might interfere with the scheme proposed by Dr. Meyer. As soon as these people were collected together in certain localities, the people felt that something had happened; the landlord lost because of the proximity of a consumptive hospital. All this might be combated by increased knowledge, on the part of the people at large, as to the danger of infection. In 1900 a bill was passed which directed the city to take action in apportioning $350,000 for such a hospital as this. He believed that there was no department that had to do with such matters in the city or the State that was not in favor of the indorsement of that bill. It all lay in the hands of one man, Mayor Van Wyck. Very few realized the pressure brought to bear upon the mayor. Physicians in large numbers urged its passage; representatives from the State and different societies petitioned, and fifteen hundred physicians signed a petition in favor of approval of the bill. The mayor, for some occult reason, failed to sign the bill. It seemed to him that by education should be meant the education of the mayor, of the board of estimate, and of the board of apportionment.

Dr. Leonard Weber said that it had been shown by long experience that the care and treatment which the poor tuberculosis patients in the incipient stage needed, in order to be cured and cease to be a menace to those around him, could not be provided in tenements nor in the city hospitals. Such patients should be treated in a properly located sanatorium, which need not be far away from the city, and they would be greatly improved in a short time and have a chance of getting well. Greater New York ought to have two sanatoria for this class of the sick poor, located about thirty-five miles away from the city, to the east and west of the Hudson River. In a measure these sanatoria might be made self-supporting by charging each patient $5 per week, to be paid by him, or by the borough to which he belonged if he be a pauper. Inasmuch as the tuberculous poor generally applied first to one of the dispensaries for treatment, Dr. Weber believed that it would be good and proper to have a special department for pulmonary tuberculosis at every dispensary, so conducted that the patient would be thoroughly examined, his sputa at once submitted to the bacteriologist of such department, and the necessary treatment conscientiously and liberally ordered for him. The physicians in charge should be given authority by the commissioners to send the sufferer to the city sanatorium when necessary.

Dr. S. Adolf Knopf said that this could not be solved by any one method. He thought there should be institutions for incipient as well as for advanced cases of tuberculosis. He thought that if $250,000 could be got it should be taken at once. Part of it should be given to the board of health for its work in purifying the tenements; another portion should be given for the erection of a hospital for the advanced cases; another portion should be given for the erection of a hospital for the incipient cases. He asked that a combined effort should be made.

Dr. John A. Wyeth then offered the following:

Whereas, A law permitting the city of New York to erect a sanatorium outside of its corporate limits for the treatment of the consumptive poor was passed by the legislature in 1899; therefore, be it

Resolved, That the municipal authorities be urged to take action under this law, and that in the furtherance of this object a committee of three be appointed by the chair to bring the matter before the council of the Academy.

SECTION ON OBSTETRICS AND GYNÆCOLOGY.

Stated Meeting, October 25, 1900.

J. Riddle Goffe, M.D., Chairman.

Demonstration of Uterine Myomata, with Remarks on the Attachment of the Bladder to the Anterior Surface of Uterine Tumors.—Dr. J. A. Schmitt presented these two specimens of uterine myoma removed from women respectively thirty-six and forty-two years of age. The operations had been difficult because of the extensive adhesions present. Dr. Schmitt said that when the bladder was found embedded in front of the peritoneum, the operator was justified in making a diagnosis of infantile bladder. In those rare cases in which the bladder was adherent to the parietal peritoneum, or in which a uterine tumor pressed the bladder against the abdominal wall, one might be misled, but careful examination should lead to a knowledge of the true condition present. The vesico-uterine cul-de-sac was always more or less preserved.

Dr. H. J. Garrigues said that these cases were rather rare. He had seen one operated upon many years ago by Dr. T. G. Thomas, and the description had been published subsequently. In that case the tumor was ovarian, and the bladder was situated about midway between the umbilicus and the ensiform cartilage. Dr. Thomas had cut into the bladder and inserted his fingers in order to determine the attachments. After having detached the circumference, he had discovered that the posterior border of the bladder was not adherent. After the removal of the cyst the operator had included the edge of the bladder in the edges of the abdominal wound. Dr. Garrigues then alluded to the case that he had reported, one in which he thought the term "fœtal bladder" was warranted. The bladder in this case had extended up to the umbilicus.

Dr. Schmitt replied that he considered the designation infantile bladder more appropriate. In some cases the infantile bladder persisted; in others, it changed from the conical to the ovoid shape. The urachus had nothing whatever to do with the infantile bladder, because the lower part of the allantois was formed into the bladder.

Hyaline Degeneration of a Fibromyoma of the Uterus.—Dr. Garrigues presented a specimen showing hyaline degeneration of a fibroma of the uterus. The specimen had been removed from a woman forty-five years of age, who had lost flesh and had suffered from backache for some years. On palpation he had felt a non-sensitive tumor of considerable size in Douglas' pouch, and in front of this he thought he had felt a small uterus. He had, therefore, diagnosed an ovarian cyst. On performing abdominal section he had found that what he had taken to be the uterus was the hypertrophied cervix. The interior of the mass was filled with gelatinous and degenerating myomatous tissue. These cases had formerly been described as fibro-cysts of the uterus.

Dr. H. N. Vineberg said that the case was of interest because the patient had nearly reached the menopause, and still had a fibroid tumor requiring removal. Within a comparatively short time he had been called upon to operate upon twelve women, all near the menopause, and presenting various forms of fibroid tumor.

Analgesia in Obstetrics Produced by Medullary Injections of Cocaine.—Dr. S. Marx read this paper. He presented a tabulated record of the conduct of forty-two cases of labor in which medullary analgesia had been employed almost from beginning to end. At first, he had made use of eucaine, but with practically no results, although it had been given in heroic doses. He had now abandoned it altogether. Some of his failures had been due to the inertness of the cocaine from its having been repeatedly sterilized by heat. After various experiments he had come to the conclusion that the best way was to carry two sealed vials, one containing gr. ss. of the muriate of cocaine, and the other ♏ xxx. of sterile water. When mixed together, ♏ x. of the resulting solution represented gr. $\frac{1}{6}$ of cocaine. In obstetrics he had yet to record a failure with this method of anæsthesia, and he had been so deeply impressed with its efficacy, as well as with its safety, that he would be perfectly willing to make use of it in his own family.

Dangers.—He recognized only two dangers from it, viz., sepsis and cocaine poisoning. In all of the cases reported there had been no symptoms of cocaine toxicity. Some of the symptoms observed might have been attributed to cocaine toxicity had it not been that the same symptoms had been observed in control tests in which cocaine had not been used at all. They were in reality due to spinal shock, or to a disturbance of the equilibrium inside of the spinal canal. Cocaine, like chloroform, was a specially safe anæsthetic in obstetrics. He believed the dangerous symptoms associated with cocaine poisoning were owing to cerebral anæmia, and hence grave symptoms of this kind were not likely to arise during labor, in which cerebral congestion was commonly present.

Technique.—After a large experience he had seen no occasion to change the technique first adopted and already described. He maintained, Dr. Corning's statement to the contrary notwithstanding, that it was absolutely necessary to inject the solution into the spinal canal. The same technique had for some reason failed him in gynæcological work. A needle three or four inches long, of fine temper, and with a short bevel, should be selected. Long needle-points might penetrate beyond the point of selection and do injury. The trocar point was the preferable one. To insure absence of pain from the puncture in the skin, a freezing-spray might be used. In a period of from two to thirty minutes the anæsthesia was ushered in, often rather suddenly. The operation could usually be begun as soon as firm pinching of the labia majora caused no pain. Transient vomiting was apt to be associated with the ushering in of the anæsthesia. Some annoyance had resulted from severe headache. This could be avoided by giving gr. xxx. or xl. of bromide about two hours previously. If this were not sufficient, gr. $\frac{1}{150}$ of hyoscine might be given subcutaneously in the anæsthetic area. He reserved nitroglycerin for cases exhibiting more disturbance together with cyanosis. When anæsthesia was complete spontaneous bearing down did not occur, but when the patient was told to bear down she did so as vigorously as when not anæsthetized. Explorations, versions, extractions, and forceps operations had been done, not with as great ease as under chloroform, but much more easily than when no anæsthetic had been given. There was no greater disposition to bleeding than in ordinary cases. His rule in the hospital had been to inject when the pains became severe. The method was specially suited to allaying the dreadful pains of normal labor. The ease with which the cervix could be dilated in a cocainized woman was a matter worthy of note. The method was effective and safe for both mother and child. It was true that failures would sometimes occur, and probably under the most humiliating circumstances, but there was no contraindication to the use of chloroform under such circumstances.

Some Observations on Medullary Analgesia.—Dr. S. Ormond Goldan read this paper, which was based on the use of the new method in twenty cases of various kinds. That this method was superior to the three general anæsthetics ordinarily in use he did not believe. To prevent rusting of steel needles from boiling and sterilization, they should be dried in the flame of an alcohol lamp. A platinum needle was too

soft. He now recommended the use of an "attenuated" needle of fourteen-karat gold having a short bevel. He preferred, as did Dr. Marx, the use of a metal syringe with a solid metal piston. He carried the cocaine divided into powders, each one being wrapped in tinfoil and containing gr. ¼. A line joining the crests of the ilia would indicate the location of the lower border of the fourth lumbar vertebra, and it was between the fourth and fifth lumbar vertebræ that the puncture should be made, and not more than 1 cm. to the outside. The needle should be thrust through the integument quickly, and then, after a pause to allow the patient time to recover from the first slight shock, it was slowly pushed forward into the spinal canal. For abdominal cases an anæsthesia lasting an hour and a half would probably be sufficient, but it should be remembered that sometimes when the lower extremities were still anæsthetic the patient would experience painful sensations from manipulations in the abdomen. Vomiting occurred in about half of the patients. Many of them were pale and slightly cyanosed at first, but later the face became suffused. More or less profuse perspiration was observed in all but two cases, probably as a result of paralysis of the sympathetic. There was a slight rise of temperature in most of the cases. Headache was present in about half of the patients; in four it was quite intense. Two of the patients had muscular rigidity of the back muscles and of the back of the head. In one patient this had persisted for one week. Anæsthesia was not induced in three cases. Toxic symptoms had appeared in one case—an obstetrical case. This patient had a very intense headache for two days following the injection. Cocaine introduced into the subarachnoid space differed in its action in no way from that observed when it was injected into the general circulation, except that it was possibly less toxic. Some patients were easily influenced by small doses; others required comparatively large doses. Large, healthy individuals were often influenced by small doses, while feeble and sickly persons might not be susceptible to quite large doses. It was curious that when the first injection failed to produce satisfactory anæsthesia it also failed to give rise to the characteristic physiological effects. The individual susceptibility of the patient to cocaine must be determined in the same way as in giving morphine to a stranger. It had been said that no mortality had been reported as following intraspinal cocainization, but he was under the impression that Tuffier had reported one death attributable to the cocaine. The majority of patients would prefer not to be conscious when operated upon. Anæsthesia by intraspinal cocainization he believed would have a place in surgery, not generally, but when for various reasons general anæsthetics could not or should not be administered.

Medullary Injections in Gynæcology.—Dr. J. Riddle Goffe made some remarks on this subject. He said that the field of usefulness of this new method of inducing anæsthesia had been greatly extended until it was now possible to operate on every part of the body from the tips of the toes up to and including the breasts. On September 27th he had seen one of Tuffier's assistants remove a small fibroid tumor of the breast under medullary analgesia. For these high operations it was not necessary to make the injections any higher than the fourth space, but larger doses of cocaine were required. It had also been observed that the line of anæsthesia extended higher than usual when the injection was made quickly or forcibly. Tuffier had very recently declared to the speaker that the dosage in the future would be higher than hitherto. Dr. Goffe said he believed the method could be relied upon in all obstetrical and gynæcological operations. Reasonable explanations had been offered for almost all of the failures so far encountered. Tuffier regarded the method as absolutely safe if rigid asepsis was maintained. A letter was read from Dr. Keen, in which he said that he had just used eucaine with perfect satisfaction. In gynæcological work there were, of course, psychological and æsthetic reasons for not using this method in ordinary cases. Tuffier insisted that the patient should sit on a table, not near the edge, but far back, as in the latter position the patient was not so liable suddenly to straighten out and deflect the needle.

Annoying Features.—Dr. A. Palmer Dudley said that he had tried this method of anæsthesia in only a comparatively small number of cases of general surgery, but in enough to make him far from enthusiastic regarding it. He referred to six cases, viz.: (1) A large abscess of the liver; (2) a hysterectomy; (3) a double ovariotomy for extra-uterine pregnancy; (4) for laceration of the perineum; (5) an amputation of a portion of the foot, and (6) an operation for the reopening of an old hernial abscess. One of the disagreeable features of this form of anæsthesia had been the associated nausea. In his judgment, it was safer to make the injection gradually. Symptoms of cocaine poisoning had been marked in most of his cases. The method advocated a short time ago by Tuffier had been to use a solution of cocaine that had been heated to 80° C. for three hours each day for three days in succession. It was evident from what had been said already that this technique had since been materially changed. In four of his cases an annoying feature had been involuntary stools. The retching was exceedingly embarrassing in abdominal work. The intense headache seemed to him much worse than the after-effects of ether or chloroform. General surgical cases certainly must be as carefully prepared as for ether or chloroform. If it became necessary to lengthen the operation more than had been anticipated, it would often be not at all easy to turn the patient over and give another intraspinal injection.

Duration of the Anæsthesia.—In his first case he had injected 1 c.c. Anæsthesia had been obtained in eight minutes, and had lasted one hour and fifty-eight minutes. There was no vomiting, but the patient had an involuntary stool. In the next case the anæsthesia had lasted for two hours and thirty-nine minutes. There was vomiting, which was controlled by an injection of citrated caffeine. The next patient received 1.5 c.c., and the anæsthesia lasted two hours and ten minutes. There were vomiting and an involuntary stool. The same quantity of cocaine solution was used in the next case, and the anæsthesia lasted one hour and twenty-eight minutes. There was vomiting here also, but no stool. In the next case the same dose had been used, and the operation had lasted one hour and sixteen minutes. In all but one case the temperature had risen to 101.5° or 102° F. within an hour. In the last case the anæsthesia had been induced in six minutes, but had lasted only thirty-two minutes. The dose in this case was 1 c.c. The method seemed to him more useful in obstetrics than in general surgery; it was also useful in cases of disease of the heart or of the kidney, bearing in mind, however, the deleterious effects of the cocaine and of nausea and vomiting in such cases. The method might be considered useful in certain cases of minor surgery in which the patient objected to taking a general anæsthetic.

A Typically Successful Case.—Dr. Henry C. Coe said that he had used the method in only one case, but that had been an extremely typical one. The patient was a virgin who had passed the menopause and had had a disease of long standing, for which she had been tapped eight times. On examination, there was a well-marked dropsy and œdema of

the lower extremities and of the lower portion of the back. Examination per rectum showed a diffuse mass in the pelvis. The probable diagnosis was a papillomatous cyst. On account of the œdema the injection had been made with great difficulty. Within five or six minutes anæsthesia had been complete. The patient was a woman who was almost free from nervousness, and who had been tapped sufficiently often to have lost any fright she might have had—indeed, she said that the tappings had always been "disagreeable." She talked during the whole operation, and showed no signs of discomfort. The adhesions were numerous, and the operation was rather difficult. She was given gr. xx. of bromide half an hour before the induction of anæsthesia. When seen the next day she was extremely comfortable and had been able to take food from the first. She made an uninterrupted recovery. This was a case in which he felt sure it would have been very risky to etherize; such a course would probably have led to a fatal termination. The pulse had been 140 at the time she had been on the table, but probably this was largely owing to the action of the cocaine. He thought he would have to wait some time before he found another patient that he considered a suitable case, particularly as the patients at the hospital were largely excitable Italians and Hungarians.

A Humiliating Experience.—Dr. E. H. Grandin said that it was with considerable satisfaction that he found the general opinion prevailing here was not quite so optimistic as he had expected from articles that had appeared in the medical and lay press. The occasion reminded him of his student days when Dr. Bigelow used to come into the operating-theatre of the Massachusetts General Hospital and tell of the horrors of the pre-anæsthetic days. That was his frame of mind at present; he was so horrified that he did not care to try the method of intraspinal cocainization for a long time to come. His clinical material consisted largely of highly nervous Italians, and hence the difficulties, though he confessed that this was the only class of people upon whom he would care to try the plan. If such difficulties were experienced among this class of people, how could one expect to use the method in private practice? The first time he had tried it Dr. Marx had given the injection, and after about eighteen minutes anæsthesia had been induced. He had then made one sweeping incision down to the peritoneum, but on endeavoring to proceed further the patient's sensations had been such that he had administered chloroform and completed the operation. In another case he had proceeded to do a vaginal section after Dr. Marx had very skilfully administered gr. ⅓ of cocaine by spinal puncture. This patient had made such a noise that the next patient refused to be operated upon. The lumbar puncture had been most skilfully performed, but the anæsthesia, at least while the patients were in the operating-room, had not been a brilliant success. Continuing, Dr. Grandin said that he had probably witnessed upward of eight thousand anæsthetizations, and had made use of chloroform, ether, and nitrous oxide. He had yet to see a death which could be traced to these anæsthetics if these had been administered by a competent person. He had seen very little nausea after the administration of chloroform. In one case he had observed suppression of urine and death after etherization, but this woman had been drenched with ether. He had found nitrous oxide sufficient for plastic work, for a posterior vaginal section, and for simple vaginal hysterectomies. He could not use nitrous oxide for abdominal work because there was not sufficient relaxation of the muscles. If both cardiac and renal disease were present he would be perfectly willing to test lumbar puncture and medullary analgesia.

A Rumor of High Mortality from Intraspinal Cocainization.—The speaker said that only yesterday a gentleman, who had been present at the International Medical Congress, had given and vouched for the following astounding figures, and from another source they had been confirmed—viz., one hundred cases of lumbar puncture with five deaths; in only seventeen per cent. of the cases had anæsthesia been secured. Dr. Grandin's comment on these statistics was that, if found to be true, it would take one hundred thousand lumbar punctures to warrant any one in using this new method of anæsthesia in his own family or on his patients without having first obtained their written consent. He thought the less this method was exploited, the better. Women were to-day, he declared, talking in their sewing-circles about how they could have babies easily. It could not be denied that every case of lumbar puncture was subject to the danger of sepsis, no matter how careful the operator. He wished it to be understood that he was not condemning the method or accepting it; he would be content to sit by and wait until about twenty thousand cases had been placed on record, and then possibly he might be willing to try it again.

A More Favorable Experience.—Dr. J. Bion Bogart, of Brooklyn, said that his own experience with this method covered twenty-five cases. In this series there had been four operations for hernia, two amputations of the leg, two amputations of the great toe, one excision of the metatarsal bone of the great toe, one excision of the hip, one double osteotomy for knock-knee, and five rectal cases, so that the field of general surgery had been pretty well covered. His experience with the method had not been uniformly satisfactory, anæsthesia not having been secured in the third and fourth cases. In these the cerebro-spinal fluid had not been obtained; the cocaine had been boiled for ten minutes, and the puncture had been made between the fourth and fifth lumbar vertebræ. Since he had adopted the plan of making the puncture between the third and fourth vertebræ, securing the escape of some of the spinal fluid, and boiling the cocaine for only two minutes, there had been no failures. In the case of amputation of the leg the patient had died from a septic peritonitis, the result of an intraperitoneal injury. A careful autopsy had failed to show any injury from the puncture. The patient died within forty-eight hours after the puncture. The speaker objected to the use of the metal syringe with solid piston because it was impossible with it to tell whether the instrument was in proper working order. He had recently called for three such syringes in succession, and each one had failed to work. In only two cases had there been vomiting while the patient was in the operating-room, and that had been transient. In one case there had been an involuntary evacuation of the bowel. Of the twenty-five cases there were seven failures. One of these was a case in which an effort had been made to utilize this method of anæsthesia for the amputation of the arm, but it had not succeeded. He had used the method in both children and adults. In one of the cases of failure a very large needle had been used, and as soon as the syringe had been removed the injected fluid had run out. As the patient was a young child he had not cared to repeat the puncture, and had for this reason given chloroform. Most of his work had been done at the Kings County Hospital among a class of poor foreigners. Of the twenty-five cases six were in Italians. In connection with the statement that the bowel often showed sensitiveness to manipulation, he desired to say that one of his cases was an operation for the closure of a fecal fistula. Although this had necessitated much manipulation of the bowel, the anæsthesia had been perfect. The greatest difficulty encountered had been the fear of the patient of the primary injection. As soon as

the lumbar puncture had been made and the cocaine injected, the field of operation should be prepared, and by the time this had been done anæsthesia would be sufficient for going on with the operation. One case was that of a man with an exceedingly painful hip; it was so sensitive that he dreaded to have any one approach him. The speaker said that he disclaimed any wish to minimize the danger of infection, for this was the chief danger, but the chance of infecting the spinal cord was not very great, if only because the needle passed through so much tissue before reaching the spinal canal. This, of course, did not mean that one should not be careful about sterilizing the needle and observing the most rigid aseptic precautions.

Dr. Marx said that he had warned Dr. Grandin that the anæsthesia was not complete, yet Dr. Grandin had insisted upon beginning the operation at once. He would admit that Dr. Grandin's cases were absolute failures, but others who had had many successes had also met with some failures. It was just as wrong to condemn the method so unreservedly on an unfortunate experience in two cases, as it was to report an experience consisting of only one beautifully typical and successful case. He was of the opinion that Dr. Goldan used too large doses of cocaine, and that it was inadvisable to make use of needles with stilettes, as, if these were used, they might push a blood clot back into the subarachnoid space. It was unfortunate that Dr. Grandin should have placed on record those astounding figures, vouched for by two unknown persons. We should not condemn or praise the method on mere hearsay and rumor. He purposed to write in the near future a paper on his failures, accidents, and complications, and hoped others would do the same.

Dr. Goldan, in closing, said that his first two cases had been failures, yet he had tested the cocaine in those cases upon himself and upon another, and had in this way proved it to be active. The failure was probably attributable to the use of too large a needle. He had endeavored to make his observations uniform by employing in each instance ℥ xx. of a two-per-cent. solution of cocaine. In another case the anæsthesia had been partial and limited to one side. In three cases the anæsthesia had been perfect until the intestine had been handled, and then the patient had given evidence of pain. As these manipulations had been made toward the close of the operation, it was quite possible that the effect of the anæsthetic was beginning to wear off. In one case he had made the puncture between the fourth and fifth, and also between the third and fourth lumbar vertebræ, but had failed to obtain anæsthesia. Some days later he had resorted to the method again for a secondary operation on this person, and had on that occasion secured complete anæsthesia. He was of the opinion that the sensation of traction was entirely different from that of ordinary pain. So far, he had not had occasion to make use of a stilette to clear the needle from obstruction at the time of puncture. He did not think it made any difference as regards the anæsthesia whether the puncture was made between the fourth and fifth or between the third and fourth lumbar vertebræ. If the puncture was made in the right place there was no occasion to depress the needle; it should be simply introduced straight. He had made it a point in this investigation to report his cases just as they had been met with, both the failures and the successes.

In Appendicitis, even though the temperature be normal or only slightly elevated, it is generally conceded that an operation is indicated when the combination of a rapid pulse and respiration exists.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Twenty-eighth Annual Meeting. Held at Indianapolis, Ind., October 22, 23, 24, 25, and 26, 1900.

The Section on Bacteriology and Chemistry met at the pathological laboratory of the Central Hospital for the Insane, with the chairman of the section, Dr. Theobald Smith, of Boston, presiding. Several papers were read and discussed. Among them was one by Dr. H. L. Russell, of Madison, Wis., in which he showed the degree of heat which was necessary to destroy the tubercle bacillus in milk without injuring commercially the value of the milk. He also read the report of the committee on the bacteriology of milk in its sanitary relations. As illustrating the peculiar way by which such germs find their way into milk, an incident occurring in a hospital at Leeds, England, was related. The nurses in that institution were in the habit of taking glasses of milk from the pantry up into the sick wards several hours before the milk was drunk. An outbreak of typhoid fever occurred among the nurses. Investigation disclosed the practice to which they had been resorting, and when it was ordered discontinued the epidemic subsided.

Dr. V. A. Moore, of Ithaca, N. Y., related an account of a diphtheria epidemic which was started in that city from milk delivered by a dairyman whose family had suffered from acute tonsillitis. The eldest son, who attended to the milking of the cows, had been pronounced well and resumed his regular work, but scientific investigation demonstrated that he still had germs of the disease in his system.

The general meeting of the association was presided over by Dr. Peter H. Bryce, of Toronto, Canada. The sessions were held in the amphitheatre of the German House. Addresses of welcome were delivered by ex-President Benjamin Harrison, Governor James A. Mount, and Hon. Addison C. Harris, Minister to Austria. The response to these addresses was made by Dr. Charles A. Lindsley, of New Haven, Conn.

Car Sanitation.—The first paper presented at the general meeting was by Prof. S. H. Woodbridge, of Boston, which was the report of the committee on car sanitation. The following recommendations were reported in the paper: (1) When a passenger was known to be contagiously ill, he should be isolated in a compartment appropriately equipped and ventilated in such a manner as to separate it from the rest of the car. Through trains should be provided with rooms for the sick, as well as state-rooms, interchangeable in use. (2) The interior of passenger cars should be plain, finished with hard, smooth, and polished surfaces. (3) All furnishings should be as non-absorbent as possible. (4) Coaches should be furnished with effective means for continuously supplying not less than one thousand cubic feet of warm air an hour for each single seat, and for distributing and removing the air without troublesome draught. (5) The temperature should be regulated. (6) The cleaning of cars should be frequent and thorough. (7) Floors and sanitary and laboratory fixtures should be frequently treated with a disinfecting wash. (8) All fabrics in cars should receive sterilizing treatment. All bed and lavatory linen should be thoroughly sterilized in the process of laundering. (9) Sewage tanks and earth closets should be provided under the cars. The practice of disposing of excreta by scattering it over road-beds was dangerous. (10) Water and ice should be obtained from the purest available sources. The use of tongs in handling ice should be insisted upon. (11) The water tank should be frequently cleansed and periodically sterilized with boiling water or otherwise. (12) The public should be educated to use individual cups. Paper paraffined cups might be provided by a cent-in-the-slot device.

(13) The use of canned goods in buffet-car service makes careful inspection of such goods imperative. Fruits and all eatables before and after purchase should be stored with care to avoid all unnecessary exposure to street and car dust. (14) The filthy habit of spitting on car floors should be dealt with in a manner to cause its prompt discontinuance. It should be punished as one of the most flagrant of the thoughtless offences against the public right to health. (15) Station premises should receive attention directed to general cleanliness of floors, furnishings, air, sanitaries, lavatories, platforms, and approaches, and should be plentifully supplied with approved disinfecting material. The recommendations of the committee were concurred in by the association.

Dr. J. N. Hurty, of Indianapolis, said that if the association would make a vigorous demand for white blankets for sleeping cars, instead of colored ones, it would be a great reform. The white blanket would tell its own story. Colored blankets were frequently saturated with filth.

Dr. H. M. Bracken, of Minneapolis, said that inasmuch as the travelling public paid a good price for Pullman cars, it was only right that the cars should be kept clean and in good condition. The beds were made up; people slept in them; the next morning the linen was removed, while the mattresses and blankets were thrown into the upper berths and remained there until the next night, and then were used again. It was not uncommon for people, on entering Pullman cars, to complain of the odor of stale bedding, etc.

Dr. C. H. Jones, of Baltimore, referred to tuberculous patients who travelled long distances. When the greatest care and caution were observed, the blankets used on Pullman cars were now and then spat upon by them. The attendants could not always be with such patients to cover their mouths with handkerchiefs. Railway managers should be notified of the great danger to the public from this source. When the public had been educated in this matter, a great reform would have been inaugurated.

Dr. C. P. Wilkinson, of New Orleans, stated that the chief objection to the equipment and furnishings of railway cars was that they were upholstered in absorbable material. In the extreme South rattan and steel springs were now used instead of plush and woollen furnishings.

Dr. U. O. B. Wingate, of Milwaukee, referred to the work that was being done in this direction by the International Association of Railway Surgeons, and suggested that it might be well to appoint a committee to co-operate with a similar committee of that association to do further work in car sanitation.

Dr. Hurty spoke of one railroad which was now constructing seven cars with perfectly plain interiors. The bottoms and backs of the seats could be taken out and thoroughly sterilized at the end of every run.

Dr. Domingo Orvananos, of the City of Mexico, read a supplementary report on car sanitation. Boards of health in the territories covered by the association ought to try to obtain support from the different legislatures so as to make certain provisions obligatory on railway companies, as, for instance, (1) the isolation in special cars of any persons suffering from transmissible diseases; (2) to supply guaranteed filters in the tanks of drinking-water; (3) the disinfection of bed-clothes, hangings, curtains, and towels; (4) all sleeping-cars should be provided with small disinfectant stoves for small toilet articles; (5) the absolute prohibition, under severe penalty, of expectoration on pavements; (6) all railroad cars should be provided with a sufficient number of cuspidors containing a strong disinfecting solution.

New Quarantine Methods and Changes which are Called for in Marine Sanitation.—This paper was contributed by Dr. Alvah H. Doty, of New York City (see page 681).

Prof. F. C. Robinson, of Maine, said that formerly a great deal of paper was made from rags, and he was surprised to hear that there was no danger from infectious diseases from cargoes of rags. He believed outbreaks of smallpox and other contagious diseases had been traced to rags.

Dr. H. M. Bracken vigorously controverted the statement of the essayist that healthy persons were not liable to carry disease in their clothing. Every physician of experience could cite instances of physicians who had carried contagion to healthy people.

The paper was further discussed by Drs. Wilson, Montizambert, the president, Lee, Durgin, and Jones, most of whom protested against the idea that physicians could not carry infection in their clothing.

Report of the Committee on Cause and Prevention of Infectious Diseases.—Dr. A. Walter Suiter, of Herkimer, New York, read this report. Reference was made to smallpox, which he said was on the increase, and he cited copious statistics to prove his assertion. He added the pleasing assurance that the death rate from this malady was decreasing. The latter fact must not be viewed too optimistically, because smallpox was certain, if an epidemic of it continued long enough, to develop its greatest degree of virulence. He showed the value of sanitary precautions and of vaccination by citing the fact that Porto Rico, since the United States had dominated its government, had rid itself of the disease, which before the war was very prevalent in that island. He also discussed malaria, scarlet fever, and typhoid fever, and declared himself a believer in the theory that the germs of malaria were transmitted by mosquitos in many instances. In discussing typhoid fever he referred to the declaration of Dr. Vaughan, that more than eighty per cent. of deaths among American soldiers in the Spanish war were caused by typhoid fever, and emphasized the necessity of cleanliness about military camps. He touched upon bubonic plague, and said that he did not anticipate a scourge of this disease here, but urged great sanitary precautions.

Etiology of Yellow Fever.—Dr. Walter Reed, of Washington, D. C., read a paper on this subject, it being the joint production of himself, Dr. James Carroll, Dr. A. Agramonte, and Dr. Jesse W. Lazear. A series of clinical, bacteriological, and pathological observations was narrated, comprising eighteen cases of yellow fever. Of this number eleven were designated as severe cases of the disease, with four deaths; three as well-marked cases with no deaths, and four as mild cases with no deaths. Blood cultures were made of eighteen cases during life, and of forty-eight separate cultures made from the blood on various days of the disease, and representing one hundred and fifteen bouillon inoculations and eighteen agar plates, they failed to find the bacillus icteroides in any of the tubes or plates. They failed to isolate the bacillus icteroides in eleven autopsies of yellow-fever patients. Having failed to isolate this bacillus either from the blood during life or from the blood and organs of cadavers, two courses of procedure appeared to be worthy of attention—namely, first, a careful study of the intestinal flora in yellow fever in comparison with the bacteria that might be isolated from the intestinal canal of healthy individuals in this vicinity, or of those sick with other diseases; or, second, to give attention to the theory of the propagation of yellow fever by means of the mosquito. The essayists pursued the second line of investigation by reason of the well-known facts connected with the epidemiology of this disease, and by the brilliant work of Ross and the Italian observers in connection with the theory of the propagation of malaria by the mosquito. Their ob-

servations pointed to the presence of an intermediate host, such as the mosquito, which, having taken the parasite into its stomach soon after the entrance of the patient into the non-infected house, was able, after a certain interval, to reconvey the infecting agent to other individuals, thereby converting the non-infected house into an infected house. This interval would appear to be from nine to sixteen days, allowing for the period of incubation, which agreed fairly closely with the time required for the passage of the malarial parasite from the stomach of the mosquito to its salivary glands. In view of the foregoing observations they tested the theory of Finlay on human beings. Experiments were made on eleven non-immune individuals. The mosquito used in all cases was Culex fasciatus Fabr. The results were nine negatives, two positives. The two cases reported as positive, the authors detailed at great length. Since they recorded one case in which a typical attack of yellow fever followed the bite of an infected mosquito within the usual period of incubation of the disease, and in which other sources of infection could be excluded, they felt confident that the publication of their detailed observations would excite renewed interest in the mosquito theory of the propagation of yellow fever, as first proposed by Finlay. From their studies thus far of the disease, they concluded that the bacillus icteroides stood in no causative relation to yellow fever, but, when present, should be considered as a secondary invader in this malady. The mosquito served as an intermediate host for the parasite of yellow fever.

Report of the Committee on the Etiology of Yellow Fever.—Dr. Henry B. Horlbeck, of Charleston, S. C., read this report. Reference was made to previous contributions on this subject by the committee, and a digest given of the labors of bacteriologists who had during the past twelve months devoted themselves to the study of the bacillus icteroides. The report closed with the following conclusions from an article by Proust and Wurtz, published September 7, 1900: (1) The bacillus icteroides of Sanarelli seemed to be the specific agent of yellow fever. That microorganism injected into certain animals, especially dogs, reproduced symptoms and lesions strikingly analogous to those observed in man. The toxin of this bacillus produced in animals the same effect as the microbe. The injection of this toxin into five individuals reproduced in man typical yellow fever accompanied by its symptoms and anatomical lesions. The serum of individuals attacked with yellow fever agglutinated cultures of the bacillus icteroides. (2) The bacillus had a prolonged vitality both in air and water (fresh and sea). It was certain that it was the same in the soil. Moulds favored its development. These facts confirmed conditions that had been known a long time. They explained the reawakening of yellow fever a long time after the extinction of an epidemic, and the longevity of the disease aboard vessels in bad hygienic conditions. No new prophylactic measures had come out in this knowledge of the etiology of the disease. As formerly, the prevention of yellow fever consisted in applying the measures of isolation and of disinfection, and of improving the hygienic conditions. While the numerous contributions to the cause of yellow fever were far from being conclusive, the researches made during the last few years furnished matters of information which would be guiding-stars in future investigations.

Dr. J. P. Bernaldez, of Mexico, spoke of human vaccine as a prophylactic of smallpox, and discussed its advantages and disadvantages.

Dr. M. S. Iglesias, of Vera Cruz, Mexico, spoke of the elements of defence against infectio-contagious diseases at the port of Vera Cruz.

Influence of Temperature on Vaccine Virus.—Dr. F. W. Elgin, of Philadelphia, read this paper. After detailing a series of experiments, he drew attention briefly to some of the lessons suggested by the experiments: (1) Vaccine points were unreliable when stored for any length of time at any temperature. (2) Virus on points might be inert, yet germs charged along with the virus remained active, causing a form of irritation somewhat resembling vaccine vesicles, and known as spurious vaccination. (3) Glycerin would not destroy the extraneous bacteria in lymph when stored at or below the freezing-point. (4) Continued exposure of germs to low temperature, when constant, did not destroy their activity and but slightly decreased their number. (5) Hot, and especially variable, temperatures speedily injured vaccine. (6) Hot temperatures increased enormously the number of germs in fluid lymph other than that stored in glycerin.

Newark's Diphtheria Antitoxin Plant.— Dr. H. C. H. Herold, of Newark, N. J., read this paper. Early in 1895, a laboratory for bacteriological research, with an attendant plant for the application of antitoxin for diphtheria, was established under the jurisdiction of the board of health in Newark. This department had been in practical operation for more than five years. The author presented the results of the experiment of establishing such a plant, and showed, by statistics of greatly reduced mortality from diphtheria by the use of antitoxin, that it was one of the best things the city officials and medical profession of that city had ever undertaken.

Presidential Address.—This was delivered by Dr. Peter H. Bryce, of Toronto, who sketched at great length the progress of sanitary science from its birth in the period of the Renaissance down to the present time, and declared that scientific workers ought to take courage from what they had seen accomplished in this century. The address was scholarly, and an admirably compact sanitary digest.

Report of the Committee on Pollution of Water Supply.—This was presented by the chairman, Mr. George W. Fuller, of New York City. The report took the form of records and summaries showing recent progress in the more important branches of the subject. With regard to quality, the water supply of the future should meet the following requirements: It should be free, or substantially free, from disease-producing germs. It should be clear and colorless, containing no noticeable turbidity or vegetable stain. It should be free from objectionable tastes and odors, as supplied to the consumer. It should be free from noticeable amounts of dissolved iron, such as make it unfit for household use. It should be free from excessive amounts of lime and magnesia, such as make water too hard for ordinary use. It should be carefully examined with regard to constituents capable of dissolving metals used in distributing pipes. Of the various branches of public works connected with the pollution of water supply, there was none in which such substantial progress had recently been made as in water purification. Ten years ago information upon this subject was very meagre, and comparatively few plants were in operation. During this period English sand-filter plants had been increased from about 1.5 to 10 acres, with respective normal capacities of about 4,000,000 and 57,000,000 gallons daily; and the American or mechanical filter plants had been increased from about 12,000 to 90,000 square feet, with respective nominal capacities of about 36,000,000 and 270,000,000 gallons daily. Projected plants for some of the largest cities in the country showed that in the next few years there would be very rapid development in the application of both of the leading methods of purification. Of the various processes for the purification of water supplies, there were two general methods which had shown distinctly their practicability—

namely, the English method of slow sand filtration, and the American method, employing rapid mechanical filters. For those waters which never possessed more than a slight or moderate amount of turbidity or dissolved vegetable color, the English method was somewhat more efficient, and as a rule it was slightly the cheaper for such waters. For those waters which for long periods at a time contained excessive quantities of either finely divided clay or of dissolved vegetable matter, there was now no practicable method of purification without the use of coagulants and subsiding basins. While coagulants could be successfully used in connection with the English method of sand filtration, the American method, in which coagulants were imperative, yielded somewhat more efficient and economical results, as a rule.

Teaching of Hygiene and Granting of Degrees of Doctor of Public Health.—Dr. Wyatt Johnston, of Montreal, compared methods of hygienic instruction in vogue in the United States and in foreign countries, with the result that the showing was decidedly favorable to the foreign countries. He inveighed strongly against the looseness of methods in this country, by which men were able to secure positions as health officers or as members of boards of health without having the necessary qualification. Dr. Johnston urged the association to consider this matter and endeavor to arrive at some standard for a purely hygienic education.

Dr. L. P. Jones, of Greenwich, Conn., followed Dr. Johnston, and outlined the following scheme for preventive medicine: (1) The endowment of a chair of preventive medicine in each of the leading medical colleges of the country; (2) the establishment of an institute, the members of which should be the incumbents of these chairs; (3) an award of prizes by this institute for essays and discoveries of special merit in sanitary science; (4) establishment of fellowships for a limited number of advanced students.

Disposal of Refuse Material. — This subject was dwelt upon by Mr. Rudolph Hering, of New York City, who presented a report in which he mentioned the methods for disposing of garbage in the great cities of the world. He referred to the progress made by European cities in this direction, and said that the present status of the disposal of garbage and refuse had resolved itself largely into a question of engineering.

Dr. Juan Brena, of Zacatecas, Mexico, dealt with the vice of smoking among youth, and offered suggestions as to the means of overcoming it.

Report of the Committee on Disinfection.—This was presented by Prof. F. C. Robinson, of Brunswick, Me. From what had been accomplished in this work, the following conclusions seemed warrantable: (1) Household disinfection after infectious diseases should combine the use of formaldehyde with other means. It could be safely relied upon for all exposed surfaces, and these only. (2) Formaldehyde required moisture enough in the air nearly to saturate it for its most efficient working. (3) There was much disagreement among experimenters as to the disinfection of tuberculous matter. One said a two-per-cent. solution of formaldehyde disinfected it; another, that even a ten-per-cent. solution did not. Several said that formaldehyde gas applied as above destroyed it; others denied this. Further experiments were needed. (4) Soap was a poor disinfectant, but one-per-cent. caustic alkali or twenty-per-cent. carbonate of alkali was efficient. (5) Carbolic acid, less than a five-per-cent. solution, had little scientific value. (6) The creosotes, as used in creolin, lysol, and solutol, were safe disinfectants. (7) Alcohol at from fifty to seventy-five per cent. had considerable disinfecting power, but not at other strengths. (8) Most metallic salts, except those of mercury, had little disinfecting action. (9) Bichloride of mercury, or corrosive sublimate, should be used in strength at least 5 : 1,000 if tuberculous matter was to be disinfected. A fresh solution was more active than one which had stood for some weeks. The addition of salts did not increase the strength of a fresh solution, but prevented it from losing its strength as rapidly. (10) Bright sunlight killed the tubercle bacillus in a few hours, and, as a rule, pathogenic bacteria retained their greatest virulence only when kept in the dark.

Dr. Jesus Chico, of Guanajuato, Mex., gave some hints about malaria from personal observations. He said he did not think the mosquito was as important a causative factor in distributing malaria as had been attributed to it, but in Mexico he thought the injudicious use of tropical fruits played an important rôle.

Miss Hester McClung, of Indianapolis, recounted the sanitary work of women in that city.

Report of the Committee to Define What Constitutes an Epidemic.—This was read by the chairman, Dr. Benjamin Lee, of Philadelphia. In the minds of the public at large, and of many of the profession, the word epidemic still conveyed an idea of universal atmospheric contamination. This was to be deplored, because while, on the one hand, its use inspired an indefinable horror and created panic, on the other hand it led to the disregard of the very precautions which were of essential use in restricting the spread of the contagion—namely, those which should be taken in regard to the person and the excreta of the patient, his effects, and his immediate environment. In view of changed views as to the propagation of communicable diseases, the word epidemic had outgrown its usefulness. It had become the means of perpetuating false conceptions, and its official use might be misleading and mischievous. Without attempting any stricter, more comprehensive, or more lucid definition of this word, the committee recommended that, as opportunity occurred, in all laws and regulations in which certain executive action was made contingent on the declaration by health authorities of the existence of an epidemic, the phraseology should be altered by omitting the word epidemic, and in place thereof inserting a brief statement of the condition calling for such action, as, for example, "whenever a communicable disease prevailed to such an extent, or was spreading with such rapidity, as in the opinion of the board to make it its duty to notify either the general public or the authorities of neighboring towns of the fact that such and such action should be taken." The report of the committee was adopted, and the committee discharged.

Report of the Committee on National Leper Home.—Dr. H. M. Bracken, of Minneapolis, chairman, presented this report. The committee dealt with the desirability of establishing national leprosaria in the United States. The records of Dr. Bracken for certain States, compared with those of Dr. Hyde, were as follows:

State.	Dr. Hyde.	Dr Bracken
North Dakota	2	2
South Dakota	..	1
Iowa	20	3
Minnesota	120	61
New Jersey	1	1
Ohio	..	1
Pennsylvania	6	6
Wisconsin	20	7

He presumed that Dr. Hyde's figures for Iowa and Wisconsin were estimated. Probably they were not too high. He had taken only those cases of which a history could be given. It is probable that the one hundred and twenty cases credited to Minnesota were taken from Dr. Hansen's report. It seemed to him that this, too, must be an estimate. If there were one hundred and twenty cases in Minnesota, the speaker

could not understand why they were not on his records. If there were that many cases in 1888, the number for Minnesota was much higher than he had given, for many of the cases in the official list could not have possibly belonged to Dr. Hansen's one hundred and twenty. It might appear from the report of cases in the Northwest that leprosy was far more common in Minnesota than in the neighboring State. He could see no reason for this belief, for the lepers in this district were among the immigrants from Norway, Sweden, Iceland, and China. These people had quite a representation in all this group of States. He could attribute the more complete returns for Minnesota only to the fact (1) that there had been less agitation against leprosy in this than in some of the neighboring States; (2) that with this lack of agitation against leprosy physicians reported their cases more willingly to the State board of health, which had endeavored during the last twenty years to palliate the sufferings of this unfortunate class; (3) that Minnesota was fortunate in having among its physicians men who were familiar with leprosy, and who were interested in philanthropic work, and these physicians had given material aid to the State authorities engaged in securing a list of all lepers in Minnesota. Several lepers in the Minnesota list gave the history of a previous residence in Wisconsin, but their names in not a single instance appeared upon the Wisconsin records. Of the thirty-seven living lepers known to be resident in the Northwest, seventeen only were in Minnesota, and there was a strong possibility of two of these being dead, but he had no positive knowledge of the fact. He did not dwell upon these facts as an alarmist, but simply reminded the association that leprosy had existed, did exist, and would continue to exist for years to come in all three countries represented in the association.

Establishment of Leprosaria.—A leprosarium should afford a comfortable home for lepers. This meant not only good buildings, but extensive grounds comprising many acres, where the lepers might have liberties and still be in exclusion. The buildings connected with the leprosarium must combine the privileges of a home and of a hospital. Those who had the disease in mild form might need little if any medical care. They needed comfortable clothing and good food. With those in whom the disease was more advanced, the care should be that of a hospital patient, with medicines to lessen their suffering and dressings that would commend themselves to any surgeon. A leprosarium should resemble modern colonies for epileptics. It should furnish employment for those who were able to work, and amusement of various kinds for all. Two of the strongest medical societies in Minnesota had placed themselves on record as favoring the establishment of national leprosaria; and the American Dermatological Association had also appointed a committee to determine the best methods to be used in the care of lepers.

By resolution the association placed itself on record as favorable to the establishment of national leprosaria.

Dr. John H. S. Fulton, of Baltimore, described a suitable dress for defence against infectious diseases.

Mr. F. H. Newell, government hydrographer, contributed a paper showing some results of the investigation of stream pollution, which had been made by the United States geological survey. The government, realizing the importance of public water supplies and their conservation and protection against pollution, had established a special division under the title of board of hydrography.

Report of the Committee on Animal Diseases and Animal Food.—This was read by Dr. D. E. Salmon, of Washington, D. C., chairman. He urged the importance of careful observations being made of glanders, in view of the fact that serum for use in the treatment of many human ailments was obtained from horses. Army horses were peculiarly liable to contract the disease in time of war, on account of the extra exertion and frequent lack of full rations during such periods. He roundly condemned the carelessness of the United States government in the matter of providing skilled and trained veterinarians in the army. He discussed the subject of hydrophobia, and emphasized the importance of active measures looking to the extermination of this disease. He cited statistics of many outbreaks of rabies, and showed the disease to be peculiarly virulent and almost invariably fatal to human beings. Misguided people, who declared that there was no such thing as hydrophobia communicated to man from animals, were sternly rebuked. Dr. Salmon declared that their obstructive tactics had wrought incalculable harm in the way of deceiving people into a careless attitude toward this malevolent disease. The Pasteur treatment was highly commended by the committee, which also recommended that the association take steps to enlighten the public on the disease and its treatment, as well as means for its prevention.

Tuberculosis.—The committee made strong recommendations on the subject of tuberculosis, asserting its belief in the theory that the disease could be and was communicated from infected cows through their milk. Here also the committee encountered learned men who controverted the theory, asserting that the difference in appearance of the bacillus of human tuberculosis and that of bovine indicated that the latter could not communicate the disease to human beings. Bovine tuberculosis was undoubtedly communicable. He inveighed against loose methods prevailing in many creameries, by which the milk received from an infected herd was mixed with the general supply of milk on hand; and, further, the practice of distributing, without previous sterilization, the waste milk and cream to be used as food for swine was condemned.

President Bryce added a few terse, vigorous utterances on the subject of the care which ought to be employed in dairies to guard against the distribution of milk infected with tubercle bacilli.

Dr. R. M. Woodward, of Washington, D. C., gave a résumé of the recent foreign work of the Marine-Hospital service.

Dr. F. F. Westbrook, of Minneapolis, reported on behalf of the committe on transportation of diseased tissue by mail, recommending that nose and throat specimens be included in one package.

Dr. Cressy L. Wilbur, of Lansing, Mich., presented the report of the committee on demography and statistics in their sanitary relations. He mentioned the progress that had been made in matters relating to vital statistics concerning which the association had acted in the past. He urged the association to stand for united and determined action in elevating the standard of registration laws in this country, and in insuring the practical success of new laws when enacted.

The following resolutions were introduced, discussed, and adopted:

1. *Resolved*, That the association, recognizing the benefits of medical school inspection, heartily approves the efforts of boards of health and of education directed toward the establishment of systems of inspection. (Offered by Dr. Adolph Gehrmann.)

2. *Resolved*, That the association approves of and encourages all efforts made by governments, whether national, state, or municipal, for the limitation of pollution of streams. (Offered by Mr. C. Monjeau.)

3. *Resolved*, That a committee of three be ap-

pointed, to be known as the committee on uniform municipal statistics, to take such steps as may seem practicable toward securing greater uniformity in all branches of municipal accounts, reports, and statistics, and particularly those branches relating to vital and sanitary statistics; said committee to have power to confer with similar committees from other societies already or hereafter appointed to the same general end, and to report at the next meeting of the association. (Offered by Dr. Leal, of Paterson, N. J.)

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. Benjamin Lee, of Philadelphia; *First Vice-President*, Mr. Rudolph Hering, of New York City; *Second Vice-President*, Dr. J. N. Hurty, of Indianapolis, Ind.; *Secretary*, Dr. Charles O. Probst, of Columbus, Ohio; *Treasurer*, Dr. Henry D. Holton, of Brattleboro, Vt.

Buffalo was selected as the place for holding the next annual meeting. The executive committee recommended that the time be fixed during the third week in September, 1901.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Annual Meeting, October 22, 1900.

GEORGE B. FOWLER, M.D., PRESIDENT.

Officers Elected.—*President*, Dr. George B. Fowler; *First Vice-President*, Dr. Charles N. Dowd; *Second Vice-President*, Dr. Irving S. Haynes; *Secretary*, Dr. John Van Doren Young; *Assistant Secretary*, Dr. Fred P. Solley; *Treasurer*, Dr. John S. Warren; *Censors*, Drs. Frank Van Fleet, Henry S. Stearns, Wendell C. Phillips, Robert Lewis, and Louis A. Rodenstein.

Report of Committee on Hygiene.—DR. HENRY DWIGHT CHAPIN, the chairman of this committee, presented a long and carefully prepared report. After quoting figures to show that there had been a tendency to a lower death rate in New York City in the past few years, probably as a result of the subsidence of epidemic influenza, and of a more careful oversight of the water and milk supplies, he took up at some length the question of the water supply as having a most important bearing on the health of the city. He said that it was a matter of grave concern to sanitarians that the water supply of Greater New York was not keeping pace with the growth in population. The Merchants' Association of New York deserved the thanks of all good citizens for its exhaustive and costly study of this matter. The boroughs of Manhattan and the Bronx were at present supplied from the Croton, Bronx, and Byram watersheds. All of the water for the borough of Manhattan and nearly all for the Bronx was furnished by the city. In the borough of Brooklyn all but about seven per cent. was furnished by the city. The borough of Queens was supplied by wells, of which about thirty per cent. only were owned by the city. The borough of Richmond was supplied by wells on Staten Island, and had practically no municipal supply. Forty-five per cent. of the city's supply was pumped, and the rest was delivered by gravity. In 1899 the average daily consumption in all the boroughs was 371,778,000 gallons, or an estimated daily consumption per capita of 103 gallons. The quantity directly available for the boroughs of Manhattan and the Bronx was about 290,000,000 gallons per day. In Brooklyn and Queens the consumption was nearly equal to the average available supply, or 116,000,000 gallons daily. The present daily supply of about 5,000,000 gallons in the borough of Richmond could not be greatly augmented without going outside the limits of that borough. It had been estimated that the consumption of water in 1903 would nearly equal the supply to the boroughs of Manhattan and Bronx at that time available under present methods. The engineers employed by the Merchants' Association had estimated that the total daily waste was nearly 150,000,000 gallons, the larger part of which was underground. Most of this waste could be avoided by putting the water mains in subways. If this amount could be saved the present water supply would be adequate until 1910. It would take most of the time between now and that date to secure the requisite additional water supply; hence the necessity for its immediate consideration. Of the various schemes which had been proposed, the best seemed to be that of taking the water from the Hudson River above Poughkeepsie. All the water that New York City would be likely to need until its population should have reached 18,000,000 could be secured in this way. The plan comprised the building of pumping-stations and filter-beds on the east side of the river, and an aqueduct from Poughkeepsie to the northern limits of the city, and of a reservoir near the northern limits. The experience of many other cities had proved beyond all question that artificial filtration, which was after all only an imitation of nature's process of converting surface water into spring water, was capable of freeing even highly polluted water from all dangerous organisms. The report closed by strongly advising that this additional water supply be placed under municipal management and control, as experience had shown that the cost to the consumer was almost always much less under public than under private ownership.

A New Gynæcological Syringe.—DR. C. A. BUCKLIN exhibited a new gynæcological syringe, one of that class which had for its object the closing of the vaginal orifice, thus enabling a douche to be taken without the use of a bed-pan.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, October 15, 1900.

PARKER SYMS, M.D., PRESIDENT.

An Improved Apparatus for the Administration of Gas and Ether.—DR. S. ORMOND GOLDAN exhibited this apparatus. A simple valve device allowed the breathing of air or gas as desired. The patient breathed back and forth into a very thin rubber bag holding about two gallons of gas. The inhaler was made of celluloid preferably. For ether inhalation, an ether chamber was slipped on between the valve and the face-piece. After breathing a few times into the gas bag, the ether was very gradually turned on. By this method all struggling was avoided and anæsthesia was quickly induced. The ether chamber could be used not only for fluid ether, but with a piece of gauze. For ether alone the ether chamber was simply attached to the face-piece, and the rubber bag added.

New Instruments.—DR. E. D. FERGUSON, of Troy, exhibited a grooved director for use in vaginal hysterectomy, and a forceps for lifting the uterus in the operation of ventral suspension. The director was intended to be passed behind the broad ligament so as to bring into full view of the operator the lateral tissues to be incised. The other instrument was intended to bring the uterus into the field of operation in ventral suspension. It was particularly useful in stout women who took ether badly. The instrument had acted well in practice, never having produced a visible abrasion of the uterus.

Address of the Retiring President: "The Need of Better Organization in the Profession."—DR. F. H. WIGGIN, on retiring from the office of president,

called attention to the fact that during his administration many important changes had occurred—*e.g.*, the change of the place of meeting to the Academy of Medicine. The most important change, aside from the advance in the regular scientific work, was the merging of the Association into the New York State Medical Association as a subordinate county association. This movement was significant, and indicated the trend of the age and the reaching out of the profession for something better in the way of State organization. It had been said by some that there was no demand for an organization that would prevent its members from being the victims of unjust suits for malpractice, but he knew positively, from personal contact with many physicians, that they did want it. For a long time to come there would be in many parts of the State very small county organizations, which would not have enough money to defend their members against unjust suits. A large and well-organized State association would be in a far better position to take up such a fight. An organization which was managed from entirely selfish interests he did not believe could succeed any more than an individual who thought of himself only could succeed. It was a most unfortunate fact that the general public had very little respect for the medical profession, and unless this profession was willing to fight for its own rights and look beyond selfish ends of individuals, the public would continue to esteem them lightly. Our legislators appreciated thoroughly the value and influence of organization, and while they would not listen to individuals they were ready to give serious consideration to petitions and propositions coming from an organized body having a membership of several thousand. We had been very blind, the speaker said, all these years, and had allowed ourselves to be trodden down largely through our own selfish indifference. An excellent example of this was found in the cry that had been raised against the taxing of certain small counties in order better to protect the rights of those living elsewhere.

Inaugural Address of the President, Dr. Parker Syms.—Dr. Syms, on assuming the chair, declared emphatically that the rapid onward strides which had placed the association in its present high position had been initiated and carried to a successful conclusion chiefly through the untiring energy of his predecessor in office. Dr. Syms then spoke of the possibilities of the future, and particularly of the crying need of improving the status of the medical profession. He sketched what he considered an ideal medical fraternity, and claimed that this idea could be realized by advancing along the line proposed by the committee on reorganization of the New York State Medical Association. Such an association must attend not only to its own members, but must look after the welfare of the public and zealously guard the public health. His address was fittingly summed up in the closing words of advice: "Honor the profession, and you will honor yourselves."

In Memoriam Dr. Lewis Albert Sayre.—Dr. John Shrady delivered this address, which was supplemented by remarks by Drs. Gouley and J. D. Bryant.

In Memoriam Dr. Samuel Smith Purple.—Dr. J. W. S. Gouley delivered this address.

Testimonial to Dr. Wiggin.—Immediately after adjournment of the association, a handsome loving-cup was presented to Dr. Wiggin as a token of appreciation of the work that he had done for the association while acting as its presiding officer.

Cancer.—Professor Czerny estimates that about seventy-five per cent. of known cases of cancer are inoperable, and that in Germany forty thousand patients die yearly of the disease.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 3, 1900:

	Cases.	Deaths.
Tuberculosis	215	131
Typhoid fever	105	23
Scarlet fever	101	0
Measles	47	1
Diphtheria	215	25
Laryngeal diphtheria (croup)	11	4
Cerebro-spinal meningitis	0	2

Medical Graduation of Women.—By a recent decision of the German Federal Council female medical students are entitled to be admitted to the State examinations in medicine, even if they have passed their preliminary examinations and received their medical education in Switzerland. As the State examinations in medicine begin in November, the medical men of Germany will very soon have the opportunity of meeting female practitioners, the number of German female students in Switzerland being rather considerable. Those ladies also who have already settled in Germany with Swiss diplomas will now be in a position to take German qualifications by passing State examination, without being forced to begin their curriculum again. The present favorable disposition of the government toward medical women has led to the rather absurd situation that female medical students enjoy privileges as to study abroad which are refused to the male sex.—*Lancet.*

The Effect of Modern Education upon Children.—The stress of modern education has enormously taxed the brains of children by the multiplicity of studies. Children cannot assimilate the ideas in widely differing department of knowledge at one and the same time. The effort to do so deranges in many instances the entire nervous system of the child. The so-called nervous child is not only not normal, but may be the victim of the education methods of the present day. The examination system is often a horror to such a child, as the writer knows from his own experience. The studies required of a growing child should never be allowed to disturb the health or interfere with proper rest and exercise. The modern city child seems to be unable to endure the burdens of civilized life as easily as did the children of the past, who were brought up in the country and spent the greater part of the time in the fresh open air. Whether our fathers were more hardy and robust as children than the progeny of the present generation may be an open question, but certainly the conditions of civilized life have so completely changed that at the present day mental and physical education possess equal importance for the growing child. The mind of the child to-day is too often developed at the expense of its vitality and health.—W. M. D'Aubigné Cahart, M.D.

Veterinary Surgeons in the Army.—The New York Sunday *Tribune* contains a readable article on the importance of the animal branch of the medical profession. After referring to the consideration with which the veterinary surgeon is treated in Great Britain, as recently evidenced by the widespread expressions of regret called forth from all sides at the death of Sir Henry Simpson, veterinary-surgeon-in-chief to the Queen, and by the bestowal of commissions on the British army veterinary surgeons, the article calls at-

tention to the fact that no commission is given to the veterinary surgons in the United States army. In fact, in England and the rest of Europe military veterinary surgeons are really officers, while surgeons are not. The latter are protected in the field by the Geneva Red Cross and considered as non-belligerents, the "vets" being regarded as full-fledged combatants, as much so as any other regimental or staff officers, running, therefore, the same risk of capture, imprisonment, or death at the hands of the enemy.

Should Consumptives Marry?—Mr. Edmund Owen, M.B., London, in the course of an address delivered before the Canadian Medical Association at Ottawa, spoke of the above subject as follows: "The extermination treatment of tuberculosis is a subject in which every member of the community should be encouraged to take a personal and intelligent interest. It is a great mistake to allow it to be regarded merely 'a doctor's question' and to wage a successful war of extermination the attack should be begun right early. It is a question which is of vital importance for the nursery, the school-room, the dwelling-house, the store, the office, the barrack, in fact it concerns every department and every period of life. The disease is everywhere, and its eradication is, therefore, a matter of concern to every one. It has not yet been shown that the offspring of tuberculous parents are born actually tuberculous, but it is beyond question that they are very prone to inherit a peculiar physical condition which renders their tissues an easy prey to the germs of the disease. The family history of many patients who, at the threshold of life, become the subjects of enlarged glands or of chronic affections of the bones or joints, gives incontrovertible evidence of there being a marked hereditary disposition in the matter of tuberculosis. So comes the question, Ought there to be a law preventing those who are undoubtedly tuberculous taking upon themselves the responsibility of parentage? There are some who would answer this affirmatively and without hesitation. But what would the church in general say to it, and what would the tuberculous minister in particular say to it? He would tell us that he reads in the very beginning of his book that he is to be 'fruitful and multiply,' and to do him justice it must be admitted that in England, at any rate, he does his best to carry out this instruction to the very letter. But let him finish his injunction, man was to be fruitful that he might replenish the earth. Now, though I do not claim to be in possession of peculiar knowledge on this point, I cannot think that the architect of the universe who 'saw everything that he had made and behold it was very good' could have desired that this beautiful world was eventually to be stocked with so large a proportion of tuberculous rubbish. I am fully conscious of the fact that I am advancing a somewhat extreme view, but surely the subject enters very largely into the question of prophylaxis. It is one, moreover, that will have to be deliberately approached and dealt with some day and that perhaps soon."

Can Life be Restored in Cases of Death from Suffocation, Chloroform-Poisoning, or Electric Shock?—In a paper by Dr. Prus (translation of which is by L. Freyberger) are detailed some experimental results of Dr. Prus on attempting to restore dogs partially killed as indicated in the title. In cases of suffocation the supply of air to the animal was shut off by clamping an India-rubber tube connecting the tracheotomy cannula with an apparatus for artificial respiration. As soon as possible after the death of the animals some of the rib cartilages in front of the heart were removed, the pericardial sac was incised, and the heart exposed. After it had been ascertained that there was no trace of any contraction of either auricles or ventricles, Professor Prus waited from fifteen to sixty minutes before he began his efforts at resuscitation. After removal of the clamp artificial respiration was started. The heart was then grasped in the right hand in such a manner that the thumb rested on the right ventricle, and the four fingers surrounded the left ventricle. Both ventricles were now compressed with moderate force, the compressions being made to imitate, as much as possible, the systolic and diastolic phases of the heart action. The interval between the stoppage of the action of the heart and respiration—in other words, the death of the animal—and the beginning of the direct massage of the heart varied in different cases from one minute to one hour. In thirty-one cases, or seventy per cent., life was restored. In chloroformed dogs under the same general conditions seventy-six per cent., and in dogs shocked by the electric current fourteen per cent., were brought to life again. An attempt to try the massaging of the heart was made on the body of an alcoholic who had committed suicide by hanging, but resulted fruitlessly.—*Treatment*, October, 1900.

Cases Simulating Glandular Fever.—J. P. Crozer Griffith says that in the minds of many physicians it is far from settled whether or no glandular fever exists as an entity. Epidemics have been reported which seem to prove that it does; but, on the other hand, cases are met with which for nearly every reason might be called instances of this disease, but in which a more careful consideration points to the glandular enlargement being of an entirely secondary nature. The author reports three illustrative cases, in which he considers the disease to have been due to influenza.—*University Medical Magazine*, October, 1900.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended November 2, 1900:

		Cases.	Deaths.
Smallpox—United States.			
Colorado, Arapahoe Co.	October 10th to 13th	2	
Costilla Co.	October 15th	1	
Ouray Co	October 9th to 16th	10	
Wild Co	September 1st to 30th	2	
Indiana, Indianapolis	October 20th	1	
Kentucky, Lexington	October 27th	2	
Michigan, Detroit	October 20th to 27th	1	
Delta Co	October 14th to 20th	1	
Maple River Township	October 14th to 20th	21	
N. Hampshire, Manchester	October 27th	1	
Ohio, Cleveland	October 20th to 27th	27	
Utah, Salt Lake City	October 20th to 27th	9	
Smallpox—Foreign.			
Austria, Trieste	October 6th to 13th	1	
Bohemia, Prague	October 6th to 13th	5	
England, Liverpool	October 6th to 13th	3	
London	October 6th to 13th	1	
France, Paris	October 6th to 13th	..	6
Germany, Solingen	October 1st to 7th	1	
India, Karachi	September 23d to 30th	1	
Mexico, Mexico	October 7th to 14th	2	1
Russia, Moscow	September 29th to October 6th	3	
Odessa	October 6th to 13th	17	1
St. Petersburg	September 29th to October 13th	18	1
Warsaw	September 29th to October 6th	..	13

DIFFERENTIAL DIAGNOSIS IN DISEASES OF THE GALL BLADDER AND DUCTS.[1]

BY GEORGE EMERSON BREWER, M.D.,

NEW YORK,

JUNIOR SURGEON TO ROOSEVELT HOSPITAL; ATTENDING SURGEON TO THE CITY HOSPITAL; INSTRUCTOR IN SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS.

WITH the possible exception of appendicitis, no subject during the past decade has received more attention from surgeons than diseases of the gall bladder and ducts.

If one refers to the standard surgical text-books of twenty years ago, there will be found practically no reference to the subject; the combined space allotted to these conditions in the works of Holmes, Bryant, Erichsen, and Ashhurst being less than thirty lines. In the treatises upon general medicine of the same period the subject is but briefly discussed, the classification made of catarrhal jaundice, gall stones, and cancer, and the treatment limited to morphine, calomel, and olive oil.

Although operations upon the gall bladder have from time to time been reported since the seventeenth century, when Stalpart van der Wiel [2] first opened the organ for the removal of a calculus, it was not until after the successful cholecystostomies of Bobbs of Indianapolis in 1867, Marion Sims in 1878, and the cholecystectomy reported by Langenbuch in 1880, that a general interest was awakened.

In his exhaustive work upon the subject published in 1890, Courvoisier[3] not only reports his own sixteen cases, and the twenty-seven cases of Kocher, Kappeler, Socin, Krönlein, Fritzche, Kouffmann, Kunz, and Niehaus, but gives in addition a complete review of all the literature of the subject, and, by a careful analysis of an exceedingly large collection of clinical reports and autopsy findings, is able to establish certain facts bearing upon the pathology and symptomatology of these conditions, which have formed the framework of our present knowledge of the subject. Since the publication of this work, many new and ingenious operations have been devised and successfully carried out, and much has been added to our knowledge of the subject; and whereas in the early days surgeons were accustomed to be content before operation with the diagnosis of cholelithiasis, or inflammation of the biliary passages, the time has now arrived when, by a proper classification of our knowledge, more accurate special diagnosis may be hoped for.

The object of this communication is, therefore, briefly to review the facts which have been gathered relating to the symptomatology of these condition and present a diagnosis chart, which will, I think, present in condensed form most of the facts bearing upon the differential diagnosis in diseases of these organs.

[1] Read by invitation before the surgical section of the Buffalo Academy of Medicine, November 5, 1900.

[2] Pantaloni: "Chirurgie du foie et des voies biliaires," 1809.

[3] "Casuistisch-statistische Beiträge zur Pathologie und Chirurgie der Gallenwege," 1890.

In preparing the chart the writer has chiefly consulted the works of Courvoisier, Waring,[1] Mayo Robson,[2] Reidel,[3] Osler,[4] and Hans Kehr,[5] as well as the papers of Fenger,[6] McCosh,[7] August Herrmann,[8] Naunyn,[9] Richardson, Mayo,[10] and others.

Perhaps the most important contribution to the subject is the recently published work of Hans Kehr, who has presented to the profession a valuable report of his four hundred and thirty-three operations on the gall bladder and ducts. In these reports the symptomatology of each case is carefully recorded, as are the actual pathological conditions found at operation or by autopsy, and his work undoubtedly furnishes the most important collection of reliable data upon the diagnosis of these diseases which has appeared.

In Part I., Chapter III., of his latest work, the writer enters a plea for more accurate special diagnosis, which he assures us can be made in the majority of instances if sufficient care be taken in obtaining the history and accurately noting the physical signs. He then presents in a masterly manner the symptomatology of the twelve different classes into which he divides these diseases, and the conditions with which they are likely to be confounded, closing the chapter with a table in which he briefly outlines the chief diagnostic points of each.

His classification, which is largely a clinical one, is as follows:

I. Stone in healthy gall bladder, cystic duct free.

II. Stone in a previously inflamed gall bladder, ducts free, adhesions.

III. Subacute cholecystitis without stone—adhesions.

IV. Acute cholecystitis with stone.

V. Acute cholecystitis in contracted gall bladder—duct closed.

VI. Hydrops of gall bladder.

VII. Empyema of gall bladder, stone in cystic duct.

VIII. Carcinoma of gall bladder.

IX. Stone in common duct—acute obstruction.

X. Stone in upper segment of common duct, chronic obstruction.

XI. Stone in common duct near papilla.

XII. Obstruction of common duct from pressure of tumor of other organs.

With a view of rendering this table more useful, the writer prepared a miniature card catalogue of these classes, jotting down at first the symptoms mentioned in Kehr's table, then adding such other symptoms and signs as are mentioned by the writer in other portions

[1] H. J. Waring: "The Diseases of the Liver, Gall Bladder, and Biliary System," London.

of the work, and occurring in the individual histories of the large number of cases reported.

To this were later added other symptoms and signs mentioned by different accurate observers and writers on the subject, either in treatises or in reports of cases, and finally such facts as he has been able to glean from his own personal observation.

During the progress of these studies it occurred to the writer that this classification, valuable as it is in its present form, might be somewhat simplified, and rendered more useful, by a slight re-arrangement which would separate pathological conditions more or less associated in the original table, and making fewer classes of purely inflammatory conditions.

Excluding such exceedingly rare conditions as actinomycosis, tuberculosis, or gumma of these organs, the natural classification would be into—

1. Calculous disease.
2. Inflammatory disease.
3. New growths.

Calculous disease of the biliary passages is of frequent occurrence, according to Reidel and Kehr, being found in ten per cent. of all adult autopsies. (The writer found it twelve times in one hundred subjects examined in the dissecting-room of the College of Physicians and Surgeons.) In perhaps ninety-five per cent. of all cases it gives rise to no symptoms (Kehr). In the remaining five per cent. it occasions symptoms which vary in intensity and importance from a slight discomfort in the right hypochondriac region to a rapidly fatal septic peritonitis.

One or more stones in a healthy gall bladder with patent ducts, produce, as a rule, no symptoms, and under these conditions the only physical signs present are those of a tumor of the gall bladder, caused by the number or size of the calculi. (The writer recently removed seven hundred and fifty-nine stones from an enormously enlarged gall bladder, which up to the time of the operation had produced absolutely no symptoms, the reason for the operative interference being the presence of a hard and irregular tumor suggesting carcinoma.)

If, however, a calculus becomes impacted at the neck of the gall bladder or in the cystic duct, or if the mucous membrane of the gall bladder becomes inflamed, symptoms are produced. In the former instance, pain of a moderate, paroxysmal character may be present, due to the expulsive efforts of the organ to rid itself of the obstruction, or to a gradual distention of the viscus with mucus; in the latter, to distention of an inflamed and sensitive organ. In the first instance the pain may occur at any time; in the latter it generally occurs during prolonged fasting, as at night, when the flow of bile is toward the gall bladder. Kehr, however, believes that the pain in these cases is practically always the result of inflammation. It is certainly a well-recognized fact that it usually begins at night, and this circumstance seems to distinguish it from the pains of gastric ulcer or other digestive disorders, which begin, as a rule, soon after a meal.

The pain originating in the gall bladder varies considerably in intensity, but presents two fairly uniform characteristics and generally extends to the back and upward to the region of the scapula and shoulder. Tenderness is rarely present in the absence of inflammation, but when present it is immediately over the organ, which usually is found behind the right rectus muscle, just below the free border of the ninth rib.

Tumor of the gall bladder, present under the conditions enumerated above, from the large size or number of gall stones, or from an accumulation of fluid, is usually more easily defined than in inflammatory conditions, on account of the absence of a pericystic exudate and of rigidity of the abdominal wall.

The presence of a number of stones in a gall bladder has occasionally been recognized during palpation by a *bruit* which, according to Petit, resembles the rubbing together of nuts in a bag. This observation has also been confirmed by Courvoisier and others.

Occasionally a stone can be distinctly palpated, as in the case reported by Lessdorf, in which he was able to grasp and appreciate the stone through the separated muscles of an umbilical hernia.

If, however, the stone becomes impacted in the cystic duct, or if the duct becomes permanently obstructed in any other manner, as by a new growth or cicatricial contraction, there occurs a gradual increase in the size of the gall bladder by an accumulation of fluid within its cavity. In the absence of infection, this fluid is sterile and consists of a thin mucus secreted by the mucous membrane, which gradually distends the gall bladder, often to an enormous size, giving rise to no discomfort excepting that produced by pressure from the size of the tumor. In this condition of hydrops of the gall bladder, the walls of the viscus become extremely thin, the fluid is at first bile stained, and later becomes cloudy and often opalescent.

A tumor of this character develops slowly, is situated immediately behind the abdominal wall below the free border of the ribs on the right side, and appears continuous with the liver at a point opposite the junction of the ninth rib with its cartilage. It develops downward and somewhat toward the median line; it moves with respiration and may permit a lateral pendulum-like motion on palpation. It is generally smooth, of even oval contour, and its consistence may be soft, hard, fluctuating, or elastic. The shape of the tumor is variable; it may be round, elongated, pear-shaped, or reniform (Reidel). A change in the size and shape of a gall bladder tumor is occasionally observed, and is probably due to a dislodgment of a previously impacted stone, or to a valve-like obstruction in the cystic or common duct. Petit reported a case in which it could be emptied by external pressure. Goldwitz and von Lucke have reported cases in which the tumor was apparently due to a paralysis from over-distention, similar to what is often observed in the urinary bladder. It may be of interest in this connection to note that the gall bladder has ocasionally been found near the median line (Kehr) or under the free border of the ribs of the left side, as reported by Raymond and Carl Beck. Congenital absence of the gall bladder has been once observed by the writer, and Courvoisier has referred to a case in which it was apparently absent, but in reality was deeply embedded in the substance of the liver.

The passage of small stones through the cystic duct may give rise to no painful symptoms. Lawson Tait, however, expressed the belief that they cause far more pain than when passing through the large common duct, and Kehr has made a similar statement. Courvoisier, however, doubts this, and reports eight autopsies in cases in which death occurred during an acute attack of biliary colic; in six of these the stone was found in the common duct, one in the gall bladder, and in one instance numerous stones were generally distributed throughout the bile passages.

The diagnosis of stone in the hepatic duct is often very difficult. Courvoisier reports fifty-two cases with fairly accurate histories. In four of these there were no symptoms, in twenty-two pain was present, without any regular type, and occasionally accompanied by digestive disturbances and vomiting. In sixteen there were enlargement of the liver and tenderness. Thirty-five had more or less jaundice (in six it was distinctly absent). In nineteen there was fever of an intermittent type. In fifteen there was a suppurative cholangitis.

The diagnosis of stone in the common duct is less

Diagnosis Chart in Diseases of the Gall Bladder and Ducts.

	Pathological condition.	Pain.	Fever.	Vomiting.	Jaundice.	Tumor of gall bladder.	Urine.	Stools.	Liver.	Spleen.	Ascites	Remarks.
I	Calculous Disease. (*a*) Stone in healthy gall bladder, ducts free.	No	No	No	No	May be present from large number or size of stones.	Negative	Normal	Not enlarged.	Not enlarged.	No	Generally discovered by accident; often unrecognized.
	(*b*) Stone in healthy gall bladder, cystic duct temporarily obstructed	May be absent; generally present during obstruction; paroxysmal	No	May be present when colic occurs.	No	May be present from distention.	Negative	Normal	Not enlarged.	Not enlarged.	No	All symptoms promptly relieved as soon as obstruction is removed.
	(*c*) Stone impacted in cystic duct.	No	No	No	No	Present; may attain large size.	Negative	Normal	Not enlarged.	Not enlarged.	No	Hydrops of gall bladder; often unrecognized.
	(*d*) Stone in hepatic duct.	Frequently present; irregular type.	Occasionally present.	May be present during pain.	Frequent	No	Contains bile pigment at times.	May be clay colored if obstruction occurs.	Frequently enlarged.	Not enlarged.	No	Diagnosis extremely difficult; symptoms generally due to coexisting cholangitis.
	(*e*) Stone in common duct; acute obstruction.	Present; acute paroxysmal radiating to back.	Generally present.	Present	Present	No	Contains bile pigment.	Clay colored.	Not enlarged.	Not enlarged.	No	Symptoms rapidly disappear when stone passes papilla.
	(*f*) Stone in common duct, movable; chronic.	Periodic attacks of acute radiating pain.	Present with chills and sweats.	Present	Present; intermittent.	Rarely present	Contains bile pigment.	Clay colored.	May be enlarged during attack.	May be enlarged from pressure of stone on vein.	No	"Fièvre intermittente hépatique" of Charcot resembles malaria; all symptoms disappear during interval.
	(*g*) Stone in common duct, impacted; chronic.	May be absent; frequently present early; may be intermittent; variable.	May be present; variable.	Often present.	Present; progressive; may vary in intensity.	Rarely present	Contains bile pigment.	Clay colored.	Enlarged	May be enlarged.	No	Condition may remain for many years; may only be jaundice with digestive disturbances and loss of weight; history of previous attacks (?) Ascites may be present from pressure of large stone or possibly from hydræmia
II	Inflammatory Disease. (*a*) Cholecystitis subacute.	Present; paroxysmal during periods of cystic duct closure from stone or swollen mucous membrane	Present during attacks of colic	May be present.	No	Present during attacks of cystic duct obstruction.	Negative	Normal	Not enlarged.	Not enlarged.	No	Tenderness over gall bladder; tendency to recurrence; generally associated with stones in gall bladder.
	(*b*) Cholecystitis acute	Acute paroxysmal radiating pain; extending to back and shoulder; may be very severe.	Present, with chills and sweats.	Present; often severe.	No	Present; tenderness; often muscular rigidity	May contain albumin and casts.	Normal	Not enlarged.	May be enlarged (sepsis).	No	May follow typhoid or other septic diseases; onset often sudden; rapid development of severe symptoms resembling appendicitis; may be necrosis of walls of gall bladder with perforation, local or general peritonitis.
	(*c*) Cholecystitis chronic (empyema of gall bladder).	Severe radiating pain at first; may disappear later; tendency to recur.	Present; severe at first, may diminish later.	Present at first.	No	Present; with tenderness; may attain large size.	Negative	Normal	Not enlarged.	Not enlarged.	No	Frequently follows acute cholecystitis; occasionally becomes quiescent, presenting practically no symptoms.
	(*d*) Cholecystitis in previously diseased and contracted gall bladder.	Present; often severe; paroxysmal.	Present; often with chills and sweats.	Present	No	No (occasionally present, due to pericystic exudate).	Negative	Normal	Not enlarged.	May be enlarged (sepsis).	No	Generally tenderness over gall-bladder area, but no tumor; local peritonitis; diagnosis often extremely difficult.
	(*e*) Cholangitis of hepatic and common ducts.	May be absent; generally present when obstruction exists, or severe infection; tenderness and pain over liver in intrahepatic cholangitis.	Present; chills; sweats; severe prostration; general sepsis.	Present	Present; variable.	No	May contain bile pigment, albumin, and casts.	May be clay colored.	Enlarged	Enlarged (sepsis).	No	Often follows severe infections of gall bladder; generally associated with stones in common or hepatic ducts; severe sepsis; generally fatal in virulent infections (streptococcus).
III	New Growths. (*a*) Carcinoma of gall bladder.	No; may occur late in disease.	No	No	Present late (portal glands).	Hard, irregular, movable tumor at first, later diffuse infiltration	Negative (at first).	May be clay colored, late.	Enlarged late in disease.	May be enlarged late (pressure on vein).	Present late.	Digestive disturbances, progressive loss of weight and asthenia; cachexia; rapidly fatal.
	(*b*) Tumor of cystic duct.	No; may occur late	No	No	No	Present when obstruction exists.	Negative	Normal	Not enlarged	Not enlarged.	No (?)	Very rare; both benign and malignant growths have been reported; diagnosis difficult.
	(*c*) Tumor of hepatic or common duct.	No; may occur late	No	No	Present; progressive.	May be present from distention with bile.	Contains bile pigment.	Clay colored.	May be enlarged.	Not enlarged	May be present late.	Very rare; diagnosis difficult.
	(*d*) Tumor of neighboring viscera producing chronic obstruction of common duct.	No; may occur late	No	No	Present; progressive; may become extreme.	Present; generally from distention with bile.	Contains bile pigment.	Clay colored.	Enlarged	May be enlarged late.	Present late.	Malignant tumors most common; chronic interstitial pancreatitis from previous infection of biliary passages may remain after cause has disappeared; enlarged portal glands; Hodgkin's disease.

obscure; the three most important symptoms are jaundice, pain, and fever. Practically all observers regard jaundice as the most constant and reliable symptom of obstruction of the common duct. When this symptom is due to calculus the diagnosis is comparatively easy; when due to other forms of obstruction it is often extremely obscure. Acute temporary common-duct obstruction from stone produces a rapidly developing jaundice, which as rapidly subsides when the stone passes into the duodenum. When the stone becomes impacted in the region of the papilla the jaundice is progressive and often becomes extreme. If, however, the dilatation of the duct above the obstruction, from an accumulation of bile, causes the stone to become dislodged, and it floats upward in the dilated common cystic or hepatic ducts, the obstruction is temporarily removed, the bile again flows into the intestine, and the jaundice disappears, only to recur when the ducts contract around the stone or it is again impacted at the papilla.

Pain in common-duct obstruction strongly points to stone. In eighty cases of calculus in the common duct reported by Courvoisier, pain was a prominent symptom in fifty-one; absent in ten; and unrecorded in nineteen.

In seventy-nine obstructions from other causes it was present in only nine instances.

In intermittent obstruction from a floating stone, it is generally more acute during the period of obstruction. It is then often paroxysmal in character, radiates to the back and shoulder, rarely is it constant and fixed in one locality. Tenderness is generally more marked nearer the median line, and slightly lower than when the gall bladder is the seat of trouble.

Fever is less constantly present, but when present is generally of a characteristic type. It was noted in nineteen of Courvoisier's cases, while in seventy-four obstructions from other causes it was present but seven times. It is often intermittent in character and is accompanied by chills and profuse sweats. This type of fever was described by Charcot as *fièvre intermittente hépatique*, and its similarity to malaria pointed out by many other observers. When present with jaundice and colic, it is almost pathognomonic of stone in the common duct. Although believed by many to be reflex or due to the absorption of bile, most modern observers agree with Schuppel in regarding it as of septic origin, as the presence in these cases of a certain degree of cholangitis is practically constant.

When the flow of bile into the intestine is hindered the urine will be dark from the presence of pigment; when completely obstructed, the stools will be clay colored.

Tumor of the gall bladder is generally absent. It has, however, been occasionally observed. Enlargement of the liver is frequent and due to the dilated intra-hepatic ducts or to an extension upward of the cholangitis, in which case there will be tenderness over the liver, and enlargement of the spleen. Ascites is present only when the obstructing stone is large and presses on the portal vein.

Inflammation of the gall bladder or ducts is present in the vast majority of patients who apply to the surgeon for relief.

Whereas it was formerly believed that biliary colic was due simply to the passage of a calculus from the gall bladder through the narrow ducts to the intestine, most surgeons now regard this symptom as the expression of an inflammatory process in these organs. Kehr states that in his opinion colic is practically always due to an inflammation of the gall bladder, and this view is also expressed by many other observers.

The fact that ninety-five per cent. of all cases of calculus present no symptoms, and the fact also that the majority of calculus cases that come to operation present, in addition, signs of inflammation, would strengthen this view.

Infection of these organs arises generally from an upward extension from the intestine, from an abnormal patency of the duodenal orifice; occasionally from some general septic disease; very rarely from traumatism. Thus Courvoisier in fifty-five cases of empyema of the gall bladder found cholelithiasis in forty-one; in two it was thought to be due to trauma, in two to general sepsis, in one to typhoid fever. Inflammation of these organs may be conveniently divided into two general classes—the mild and the severe infections; the former due to the colon or typhoid bacillus, the latter to the streptococcus or some other equally virulent organism. In the great majority of instances, cholelithiasis has preceded the inflammation and prepared the way for it.

The symptoms of cholecystitis are pain, tenderness, fever, and the presence of a tumor of the gall bladder.

In a mild infection of the organ with the ducts open, insuring free drainage into the bowel, these symptoms may be wanting. If the cystic duct becomes obstructed from stone or swelling of the mucous membrane, colicky pains occur, which may radiate to the back and shoulder; vomiting is generally present during the period of obstruction; there are usually also slight fever and general malaise, which disappear with the pain when the obstruction is relieved. Unless the gall bladder be small or deeply seated under the right lobe of the liver, a sensitive tumor may be felt during the continuance of the obstruction. These symptoms frequently subside spontaneously, but the tendency to recurrence is marked.

If chronic obstruction of the cystic duct occurs, empyema of the gall bladder results, giving rise to symptoms of varying severity, according to the virulence of the infecting agent or the resistance of the individual. This condition may also exist with open ducts, as evidenced by Courvoisier's statistics, in which he reports the ducts free in eleven of forty-one recorded cases of empyema. The pain and fever may be wanting, the only symptoms being the presence of a tender tumor in the gall-bladder region, or, in cases of a small or contracted gall bladder, only a local tenderness or muscular rigidity. In the severer cases the pain is acute, paroxysmal, and radiating, the fever is high and accompanied by chills and vomiting. A local peritonitis may be present and give rise to intra-abdominal abscess, a condition often resembling appendicitis.

In the more virulent infections the symptoms often develop with great rapidity, and are accompanied by marked prostration and a rapidly developing sepsis. Perforation of the gall bladder with a fulminating, fatal, septic, general peritonitis has been reported in a number of instances.

Jaundice is absent in cholecystitis unless the tumor of the gall bladder or cystic duct presses upon the common duct.

In inflammation of the common or hepatic ducts, however, jaundice is often present in addition to the pain and fever, but unless accompanied by stone or complete obstruction from other causes is seldom of a severe type. In the more virulent infections of the common and hepatic ducts, the process extends rapidly to the intra-hepatic branches and gives rise to general sepsis, often without other symptoms, leading, unless speedily relieved by surgical means, to multiple hepatic abscesses and death. This condition is practically always accompanied by the presence of foreign bodies in the ducts or gall bladder. In seventy-four cases analyzed by Courvoisier fifty-seven had calculi, seven ascarides, and three echinococcus.

While new growths of neighboring organs not in-

frequently produce symptoms referable to the gall bladder or ducts by external pressure or direct extension, primary new growths in these organs are exceedingly rare.

The gall bladder is most frequently affected, and in the great majority of instances the growth is carcinoma.

This disease was observed, according to Courvoisier, in seven of two thousand five hundred and twenty autopsies. In one hundred cases collected by the same author, seventeen were in males and eighty-three in females, the decade furnishing the largest number being between fifty and sixty years of age. Seven-eighths of all the cases occurred in the subjects of cholelithiasis. In sixty-six of these cases in which the history was fairly complete, the early symptoms were generally those of disturbed digestion and malnutrition. Vomiting was noted in thirty-six instances; colic in twenty-one; jaundice occurred in forty-eight instances, generally late in the disease; while in eighteen it was absent. In twelve ascites was present. Kehr states that the last two symptoms always result from an involvement of the portal glands, causing pressure on the ducts and portal vein.

The only reliable symptom which can be detected early is the presence of a hard, irregular tumor of the gall bladder. The diagnosis is exceedingly difficult; in only four of Courvoisier's one hundred cases was the nature of the disease determined during life. The disease is rapidly fatal; in fifty-three cases followed to the end, death occurred in all within nine months from the first characteristic symptoms.

The occurrence of both benign and malignant tumors within the lumen of the bile ducts has been reported by Mayo Robson and others. The symptoms at first are those of duct obstruction from other causes, and the malignant varieties are later accompanied by malnutrition, progressive asthenia, and cachexia.

Chronic obstruction of the common duct from outside pressure of tumors of the pylorus, duodenum, or head of the pancreas is of fairly frequent occurrence. As would be expected, the cardinal symptom is a progressively increasing jaundice without fever and with but little or no pain. In these cases there is a gradual enlargement of the liver and gall bladder, with ascites.

The same symptoms may be occasioned by a tumor within the duct. Intermittent jaundice has rarely been observed in such cases, probably due, as suggested by Haarimann, to sloughing of a part of the obstructing mass, allowing a temporary flow of bile into the intestine; or, as reported by Courvoisier, a pedunculated tumor near the papilla may act as a valve and occasionally permit the passage of bile.

Let us, in conclusion, briefly review the significance of the three chief symptoms occurring in diseases of the gall bladder and ducts.

Pain: The occurrence of repeated attacks of acute paroxysmal pain, in the upper right quadrant of the abdomen, strongly suggests a lesion of the biliary passages. This suggestion is accentuated if the attacks occur at night, or during fasting, and are accompanied by vomiting and fever. If the pain radiates upward to the back and shoulder, and if an area of tenderness exists under the free border of the ribs, the diagnosis is still more probable.

If in addition to the pain we have a palpable or tender tumor under the lower border of the ninth rib, in all probability the case is one of cholecystitis. If, on the other hand, there is jaundice but no gall-bladder tumor, we probably have to do with a lesion of the common duct.

Other conditions giving rise to acute pain in the upper abdomen, and to be excluded, are, first, gastric ulcer, in which the pain and tenderness are more generally located in the epigastric or left hypochondriac region, and in which fever, as a rule, is not present; appendicitis, in which vomiting and fever may also be present, but the pain and tenderness are usually located in the right lower quadrant of the abdomen; renal colic, in which the pain originates in the flank and extends downward along the ureter to the testicle, which may be retracted, and which is often accompanied by vesical irritation and hæmaturia; the gastric crisis of tabes, in which fever is absent, and although the vomiting is present, there is no characteristic point of tenderness. These cases also show an absence of the patella reflex and the presence of sensory disturbance and ataxia in the extremities. Occasionally, pain in this region, strongly simulating biliary colic, will be caused by the presence of inflammatory adhesions in the region of the pylorus and duodenum, causing a narrowing of the canal with dilatation of the stomach. Chronic intestinal obstruction, or the early pain of a local peritonitis from other causes, has given rise to difficulties in diagnosis; and lastly, syphilitic hepatitis may present pain and other symptoms almost identical with those generally found in calculous disease of the biliary passages.

Tumor: A tumor in the right hypochondriac region, which develops slowly and is preceded by a history of cholelithiasis; which is round, oblong, or pear-shaped, with a smooth convex surface, elastic or fluctuating; which lies immediately under the abdominal wall below the ribs and near the outer margin of the right rectus muscle; which moves with respiration; which allows a certain amount of lateral pendulum-like motion on account of its attachment above; which cannot be made to disappear like a movable kidney under the ribs; and which is not accompanied by pain and fever, is in all probability a gall bladder distended with mucus (hydrops). If with such a tumor there is a progressive jaundice, it is probably a gall bladder distended with bile from common-duct obstruction. If such a tumor is sensitive to the touch and is accompanied by fever it is doubtless a gall bladder distended with pus (empyema). If the tumor is ill defined on account of muscular rigidity, if there are acute radiating pain and marked tenderness in the right hypochondriac region, we have generally to do with a cholecystitis with local peritonitis. The presence of a tumor corresponding to the above description, without pain, fever, or jaundice at first, but presenting a hard, irregular surface, is in all probability cancer.

Jaundice: The occurrence of a mild transitory jaundice unaccompanied by other symptoms suggests a catarrhal obstruction of the common duct (a mild duodenitis from indigestion). The occurrence of a temporary jaundice with colic suggests the passage of a stone through the common duct into the intestine. The occurrence of intermittent jaudice, intermittent colic, and intermittent fever suggests a floating stone in the common duct. The occurrence of continued jaundice, with chills, fever, hepatic enlargement and tenderness, hypertrophy of the spleen and general sepsis, suggests an infective cholangitis. The occurrence of a progressively increasing jaundice, and enlargement of the liver, with a previous history of colic, suggests an impacted stone near the papilla. The occurrence of a progressively increasing jaundice, without pain or fever but with a tumor of the gall bladder, suggests common-duct obstruction from new growth.

Tubo-Ovarian Disease and How Best to Deal with it.—(1) In the dormant stage operate by the abdominal route. (2) In the acute stage explore by the abdominal route, then decide between completing the operation in one or two sittings. (3) Following abortion or delivery at full term, vaginal drainage often puts the patient in better shape for an abdominal section later on.—Edwin Ricketts.

THE MORTALITY FROM DIABETES MELLITUS IN THE CITY OF NEW YORK (MANHATTAN AND THE BRONX) IN 1899.

CLASSIFIED ACCORDING TO MONTH, SEX, AND AGE; ALSO AN EXPOSÉ AS TO NATIONALITY, DURATION OF RESIDENCE IN THE UNITED STATES, OCCUPATION, DIRECT CAUSES OF DEATH, AND ACCOMPANYING DISEASES.

By HEINRICH STERN, Ph.D., M.D.,

NEW YORK.

A. The Mortality from Diabetes Mellitus according to Month, Sex, and Age.[1] — A perusal of Table I. evidences that 202 deaths from diabetes mellitus were recorded. Of these, 102 took place in males and 100 in females. As in the preceding decade, 1889–1898, the greatest mortality from this affection, in 1899, occurred in the month of October. The mortality was distributed over the different seasons, as follows:

	Number of Deaths.
Spring: March, April, May	53
Summer: June, July, August	42
Fall: September, October, November	57
Winter: December, January, February	50
Total	202

The mortality among males was greater in the months of February, June, September, November, and December; it was greater among females in March, May, July, August, and October. In January and April the deaths were equally distributed between both sexes.

The greatest mortality took place between the 55th and 65th years of life; the smallest between the 10th and 15th and between the 20th and 25th years. The number of diabetics who succumbed between the 45th and 55th years was almost the same as of those who died between the 65th and 75th years. The disease terminated fatally four times oftener in males than in females between the 25th and 35th years of life. Between the 35th and 45th years the mortality of males was about twice that of females. Between the 45th and 55th years the deaths of males exceeded those of the females by about one-third. Between the 55th and 65th years the mortality of females surpassed the deaths of males by just 40 per cent. The mortality of the female sex was also higher between the 65th and 75th years, and it exceeded nearly twice the mortality of males between the 75th and 85th years.

Below the 25th year but 10 deaths ensued, of which 7 occurred in males and 3 in females. But 3 diabetics died above the 85th year—2 males and 1 female.

B. The Nationality of the Deceased Diabetics.— The greatest number of deaths (Table II.)—57—occurred among those born in Germany. Of natives of the United States, 51 succumbed to the affection. Thirty-seven of the deceased were born in Ireland, 18 in Russia and Poland, 12 in England and Scotland, 6 in Austria-Hungary-Bohemia, 6 in Holland and Belgium, 4 in Central and South America and the West Indies, 4 in Italy, 3 in France, 2 in Canada, 1 in Switzerland, and 1 in China.

These figures probably stand in some relationship to the numerical proportion of each nationality to the total populace of New York City. However, no Swedes, Norwegians, or Danes succumbed to the affection although a considerable number of New York's inhabitants are of these nationalities.

Among the American-born, 27 were males and 24 females. The mortality of males exceeded that of females also in those born in England and Scotland, Austria-Hungary-Bohemia, Holland-Belgium, and Central and South America and the West Indies. No death from diabetes was reported of females of Canadian or Italian birth.

The mortality was larger among the female sex than in that of the male in natives of Germany, Ireland, Russia-Poland, and France.

Among the 51 deaths in the American-born, many were of individuals of Irish parentage or of unmistakably Irish extraction. The high mortality of natives of Germany is not only due to their numerical strength but to the great number of German-born Jews.

The Hebrews, no doubt, are more commonly affected with chronic glycosuria than natives of the nation among whom they dwell. The death certificates of Americans furnish no direct evidence whether the deceased belonged to the Jewish race or not, nor in many instances does the name disclose the racial identity. The deceased buried in Jewish cemeteries were classed by me as Jews. A few others of undoubted Jewish origin (personal name, name of parents, place of birth) who were not interred in specific Jewish burial-grounds were also counted among the Jews. Out of the total of 202 deaths, 54, that is, almost 25 per cent., occurred in Jews. Of these, 21 were males and 33 females.

Thirty-seven of the deceased were born in Ireland. Taking the Irish as a race—as I have done with the Jews—adding those who were born outside of Ireland of Irish parentage or who are of Irish descent, we have a total mortality of at least 51—22 males and 29

[1] Some of the following data differ slightly from the figures which I gave in a recent communication. A careful search of the original certificates of death showed that the enumerator has classified the deaths from diabetes insipidus (certificates Nos. 23,282 and 36,004) and a case of death from "dilatatio cordis" (certificate No. 13,272) among the deaths from diabetes mellitus.

females. This figure also forms over 25 per cent. of the total mortality from diabetes mellitus.

The diabetics of Russian or Polish nativity, with exception of one female, were all Jews.

The frequent mortality from diabetes in certain races, as the Jews and the Irish, may be ascribed to manifold causes. Mental exertion, the characteristic modes of living, gluttony, alcoholic intoxication, etc., might be considered predisposing factors in the production of the diabetic state, but the cardinal predisposing cause, in my opinion, is the breeding in and in to which, in a very pronounced measure, the Jewish as well as the Irish race still adhere.

C. The Age of the Deceased Diabetics from the Different Nationalities and the Duration of their Residence in the United States.—Out of the 57 deceased German-born diabetics 2, 1 male and 1 female, lived above the age of 85. Eight died between the 75th and 85th years, 20 between the 65th and 75th years, 19 between the 55th and 65th years, 5 between the 45th and 55th years, 2 between the 35th and 45th years, and none between the 25th and 35th years. The average age attained by the diabetics of German nativity, excluding those who died during childhood and adolescence, was therefore almost 66 years.

Two diabetic females born in the United States died between the 75th and 85th years; 7 American-born diabetics succumbed to the malady between the 65th and 75th years; 13 between the 55th and 65th years, 5 between the 45th and 55th years, 10 between the 35th and 45th years, and 5 between the 25th and 35th years. The average age of American-born diabetics, with the exclusion of those who died before the 25th year was reached, amounted therefore to 53 years.

Of the deceased born in Ireland, 2 females lived to the period between the 65th and 75th years; 15—5 males and 10 females—to that between the 55th and 65th years; 11—5 males and 6 females—died between the 45th and 55th years; 6—3 males and 3 females—between the 35th and 45th years, and 3, all males, between the 25th and 35th years. The mean age attained by the Irish-born diabetics was therefore not quite 52 years.

One female among the diabetics of Russian birth attained an age between the 75th and 85th years; 2 diabetics of Russian nativity lived to the period between the 65th and 75th years, 6 to that between the 55th and 65th years; 5 died between the 45th and 55th years, 3 between the 35th and 45th years, and 1 between the 25th and 35th years. The average age of deceased diabetics, natives of Russia, amounted therefore to about 54½ years.

Of those born in England and Scotland, 1 lived above the 85th year, 1 until the period between the 75th and 85th years, 2 until that between the 65th and 75th years; 4 died between the 55th and 65th years, 3 between the 45th and 55th years, and 1 between the 35th and 45th years. The mean age attained by the diabetics of English or Scotch birth amounted therefore to over 61 years.

The 54 deceased diabetics of Jewish extraction attained the following ages:

Age.	Male.	Female.
1–10 years		
10–15 "		
15–20 "	1	
20–25 "		
25–35 "	1	1
35–45 "	4	2
45–55 "	4	5
55–65 "	5	11
65–75 "	4	9
75–85 "	2	4
85 years and above	..	1
Total	21	33

In the average those who had died after the 25th year of life attained an age of 60 years.

The duration of residence[1] in the United States of foreign-born deceased diabetics, for the different nations, was as follows:

Nationality.	Mean Number of Years of Residence in United States.	
	Male.	Female.
Germans	37	40
Irish	31	Not quite 36
Russians and Poles	Between 15 and 16	Between 15 and 16
English and Scotch	" 32 " 33	" 40 " 41
Austrians, Hungarians, Bohemians	17	" 20 " 21
Hollanders and Belgians	Between 36 and 37	44
Italians	13	

D. The Occupation of the Deceased Diabetics (Table III.).—The occupation of the deceased diabetic was not stated on every certificate of death. Out of a total of 102 deaths of males, the occupation of 82, and of a total of 100 deaths of females, the occupation of 44 was recorded.

[1] The question, "How long in the United States?" I found not always answered.

It may be surmised that the deceased male diabetics whose former occupation is not mentioned in their respective certificate of death belonged, in the majority, to the wealthier class of the population. This, however, is not the case. Some of the males were children; others, without an apparent occupation, passed away in public institutions where nothing was known about the deceased, and others died in the tenement-house districts. It is safe to assume that most of the 56 females whose occupation is not stated were "houseworkers," and that the attesting physician did not consider these duties a specific or definite "occupation."

TABLE III.

Occupation.	Sex and Age of Deceased.	No.	Mean Age Attained.
"Houseworkers"	F. 58, F. 60, F. 57, F. 35, F. 65, F. 62, F. 59, F. 58, F. 75, F. 58, F. 55, F. 67, F. 47, F. 69, F. 58, F. 60, F. 68, F. 66, F. 59, F. 52, F. 60, F. 47, F. 69, F. 55, F. 51, F. 62, F. 38, F. 58, F. 55, F. 70, F. 31, F. 60, F. 65, F. 75, F. 54	35	58

Storage-warehouse proprietor	M. 55	1	55
Builder	M. 63	1	63
Student	M. 15	1	15
Stonemason	M. 46	1	46
Carpenter	M. 52	1	52
Waiter	M. 69	1	69

Apart from the 35 "houseworkers"—for almost every woman of more advanced age dies as such—the greatest mortality (9) occurred among the great class of clerks, agents, salesmen, etc. The porters, janitors, watchmen, and kindred occupations furnished 7 deaths from diabetes. The same mortality from this affection took place among tailors and dressmakers. Six restaurant, hotel and barkeepers and the same number of "merchants" succumbed to diabetes. The mortality from diabetes of domestics amounted to 5, of drivers to 4, of laborers to 4, and of cigarmakers and manufacturers also to 4.

The death figures for 1889 are too small to permit of any definite conclusions as to the relationship between occupation and diabetes, or between occupation and fatal termination of the affection. One fact, however, is clearly evinced by a perusal of Table III., namely, that diabetes mellitus is not a special visitation upon the well-to-do, as is commonly supposed, but that it occurs in great frequency among the working people, among whom gluttony and leisure hours are exceptions.

Granted that of the 20 deceased male diabetics whose "occupation" is not stated, or who had "no occupation," 10 were persons of means, we still have 10 with "no occupation" whom we are compelled to classify among the poorer strata of society.

Adding to this	10
Railroad employees	2
Restaurant, hotel, barkeepers, total mortality 6; employees, say	3
Drivers	4
Porters, etc.	7
Bakers, etc., total mortality 2; employees, say	1
Peddlers	2
Clerks, etc.	9
Laundrymen	2
Cooks	2
Shoemaker	1
Tailors	6
Domestic	1
Laborers	4
Cigarmakers, total mortality 4; employees, say	2
Typesetter	1
Police officers	2
Gardeners	2
Engraver	1
Color mixer	1
Stonemason	1
Carpenter	1
Waiter	1

We have at least 66 of the 102 deceased males who were working for a livelihood or who were dependents upon others.

Besides, some of the professionals, whom I have entirely omitted from this last calculation, in all likelihood belonged to the poorer classes; and it is possible that some of the "merchants" even were not wealthy people. In looking over the records of the last places of residence of the deceased, the fact that the working classes are more frequently the victims of diabetes than are the so-called upper strata of the populace is once more confirmed.

E. The Direct Causes of Deaths.—1. COMA (Table IV.).—Among a mortality from diabetes of 202, death supervened 60 times by coma.

I have stated elsewhere[1] that "the greater number of these 60 instances which were designated as 'coma,' it is safe to assume, were not those of typical diabetic coma. Coma, associated with diabetes, deserves the appellation 'diabetic coma' only in certain well-defined instances."

In Table IV. I have collected the 60 cases of coma. The following facts are elucidated by it:

[1] "On Coma Diabeticum and its Treatment," meeting of American Medical Association, Section Materia Medica and Therapeutics, June 5, 1900, to be published in Journal of the American Medical Association.

Nationality: Of those who died in coma were born in

	Total.	Male.	Female.
United States	19	6	13
Germany	16	8	8
Ireland	8	4	4
Russia, Poland	7	3	4
England, Scotland	4	3	1
Austria, Hungary, Bohemia	2	..	2
Holland	2	..	2
Italy	1	1	..
West Indies	1	1	..
Total	60	26	34

Of these 60 who have died in coma, 23, 8 males and 15 females were Jews.

While the proportion of the total coma cases to the total mortality from diabetes is 60 to 202, or 29 per cent., coma occurred in 43 per cent. of the fatal cases of diabetes in the Hebrews.

Sex: Of the diabetics who have died in coma 26 were males and 34 females.

Age: The lowest age of any diabetic who has died in coma in 1899 in the City of New York was 15 years, the highest 83 years and 2 months. The mean age of all who have died in coma amounted to 53 years and about 3 months. The mean age of the males was 49 years and about 6 months, that of the females 56 years and almost 2 months.

TABLE IV.

Sculptor	1
Dressmaker	1
Domestic	1
Total	34

Duration of diabetes mellitus before coma ensued: In but few instances—in fact, too few to be of any definite value—was the duration of the affection, prior to the establishment of coma, recorded. The average duration of the 9 recorded instances amounted to 4 years and 5 months.

Duration of coma: But 9 certificates give information as to the duration of the comatose condition. This varied from two hours in one instance to one week in another. The mean duration of the comatose state in these 9 instances was a trifle over 44 hours.

Diseases and conditions concurring with the cases of diabetes mellitus which terminated in coma:

	Occurred in
Carbuncle	2 instances.
Cellulitis	2 "
Diabetic gangrene	4 "
Mastoiditis	1 instance.
Nephritis	4 instances.
Paralysis cordis	4 "
Exhaustion / Asthenia / Old age (without specification)	7 "
Paralysis (without specification)	1 instance.
Respiratory failure	1 "
Pulmonary phthisis	2 instances.
Pneumonia	2 "
Myocarditis	1 instance.
Gastro enteritis	1 "
Convulsions (no specification)	1 "
Thrombus	1 "
Arteriosclerosis	1 "

[1] It may be of interest to learn that 13 out of these 60 patients died in public hospitals. While a few—probably three—of those who died in hospitals were "pay patients"; the vast majority, on the other hand, were "charity patients."

4. Septicæmia.[1]—Table VII.

No. of Certificate of Death.	Nationality.	Sex.	Age.	Duration of Diabetes Mellitus.	Occupation.	Extract from Certificate of Death.
Manhattan Bor.						
8,580	Austria	M.	56		Police officer	Gangrene of foot, septic parotitis, general sepsis.
12,224	Germany	M.	70		No occupation	Chronic nephritis (6 mos.), gangrene of leg, septic fever (1 week).
13,990	Russia	M.	67		Collector	Gangrene of foot, septicæmia.
16,725	Holland	M.	63	3 years	Cigarmaker	Gangrene of foot.
17,665	Ireland	F.	72		Domestic	Gangrene of leg.
18,923	Bohemia	M.	39		Saloonkeeper	Septicæmia.

I made no attempt to classify the 30 remaining instances according to the immediate cause of death. In the majority of the certificates no direct cause is stated. Besides this, most of these instances occurred together with chronic affections such as phthisis or nephritis, from which death may have resulted just as frequently as from diabetes, *per se*.

F. Accompanying Affections.—

1. Phthisis Pulmonum.—Table XI.

Nationality.	Sex.	Age.	Duration of Diabetes Mellitus.		Occupation.	Remarks (Extract from Certificate of Death).
			Years.	Months.		
Germany	M.	58	5	..	Cattle dealer	Phthisis pulmonum, duration six months.
Germany	F.	59	..	..	Housewife	Pulmonary tuberculosis.
Russia	M.	56	2	6	Hotel keeper	Consumption, duration one year.
Russia	M.	35	..	..	Peddler	Acute pulmonary tuberculosis; coma.
United States	M.	34	..	..	Salesman	Tuberculosis; nephritis.
Ireland	M.	57	..	..	Clergyman	Acute pulmonary tuberculosis.
United States	M.	14	..	..	Not stated	Pulmonary tuberculosis.
Russia	M.	40	..	..	Not stated	Phthisis; coma.

2. Nephritis and Other Affections of the Kidney.—Table XII.

Nationality.	Sex.	Age.	Duration of Diabetes Mellitus.	Occupation.	Remarks (Extract from Certificate of Death).
United States (col.)	M.	36	.....	Cook	Chronic diffuse nephritis.
Germany	F.	57	.....	Housewife	Interstitial nephritis; aortic stenosis; arterio-sclerosis.
Germany	F.	66	.....	No occupation	Chronic Bright's disease; chronic myocarditis.
Scotland	M.	35	.....	Typesetter	Chronic diffuse nephritis; diabetic coma.
Germany	M.	70	.....	No occupation	Chronic nephritis; gangrene; septic fever.
Russia	M.	45	.....	Merchant	Nephritis.
Belgium	M.	50	.....	Cook	Nephritis; gangrene.
Canada	M.	48	.....	Bookkeeper	Uræmia (not stated that nephritis existed).

United States	F.	75	.....	Not stated.	
Germany	F.	65	.....	Housewife	Gangrene of foot.
Germany	M.	60	.....	Wine merchant	Gangrene of left thigh.
Germany	M.	61	.....	Agent	Gangrene of right leg.
Ireland	M.	55	.....	Storage warehouse prop.	
United States	F.	57	.....	Not stated	Gangrene of thigh.
Ireland	M.	60	.....	Porter.	

4. Arteriosclerosis.—Table XIV.

Nationality.	Sex.	Age.	Duration of Diabetes Mellitus.	Occupation.	Remarks (Extract from Certificate of Death).
Germany	F.	57	.....	Housewife	Arteriosclerosis; aortic stenosis.
Holland	F.	75	.....	No occupation	Arteriosclerosis; neuritis.
Germany	M.	72	.....	Not stated	Arteriosclerosis.

5. Cardiac Dilatation.—Table XV.

Nationality.	Sex.	Age.	Duration of Diabetes Mellitus.	Occupation.	Remarks (Extract from Certificate of Death).
Germany	M.	63	.....	Not stated	Dilatation of heart.
Germany	F.	68	.....	Not stated	Dilatation of heart.

6. Paralysis (Excluding Cardiac Paralysis).—Table XVI.

Nationality.	Sex.	Age.	Duration of Diabetes Mellitus.	Occupation.	Remarks (Extract from Certificate of Death).
Holland	F.	71	3 years.	No occupation	Paralysis; coma.
Germany	M.	85	.....	Tailor	General paralysis; bronchitis.

7. Various Other Accompanying Conditions and Disorders.—Table XVII.

Nationality.	Sex.	Age.	Duration of Diabetes Mellitus.	Occupation.	Remarks (Concurring or Intercurring Affections).
Scotland	F.	62	.....	Housewife	Gastro-duodenitis.
Russia-Poland	F.	55	.....	Housewife	Lobular pneumonia.
United States	F.	42	.....	Sculptor	Hypostatic pneumonia.
Germany	M.	74	.....	Merchant	Thrombus left median vein.
Germany	F.	66	.....	Not stated	Myelitis.
Germany	F.	54	.....	Not stated	Acute dysentery.
United States	M.	69	.....	Watchman	Erysipelas; fistula in ano.
Ireland	M.	52	.....	Police officer	Chronic bronchitis.
Germany	M.	69	.....	Waiter	Pulmonary embolism.
England	F.	70	.....	Housewife	Acute diarrhœa.
United States	F.	31	.....	Housewife	Acute gastro-enteritis.
Ireland	M.	52	.....	Laborer	Acute rheumatism.
United States	F.	60	1 year.	No occupation	Phlebitis of leg; cerebral embolism.

It is a deplorable fact that many practitioners habitually omit to furnish the exact and complete data connected with a case of death. This is especially true of the young hospital internes. A statistical attempt, like this one, can serve a definite purpose only if all the facts pretaining to a case of death have been conscientiously reported.

Inasmuch as the recognition of the chief and contributing causes of death depend entirely upon the amount of attention devoted by and the ability of the medical attendant, the value of the various certificates, emanating from so many sources, for statistical studies must naturally differ.

Many cases treated for "diabetes" or glycosuria are neither "diabetes" nor glycosuria. On the other hand, diabetes mellitus is not infrequently entirely overlooked and many a certificate of death containing the insignificant words "inanition," "asthenia," "exhaustion," etc., affixed to the name for some acute disorder, should instead bear the designation "diabetes mellitus."

56 East Seventy-Sixth Street.

THE USE OF THE SUPRARENAL CAPSULE IN DISEASES OF THE LOWER AIR PASSAGES. A PRELIMINARY REPORT.

By SAMUEL FLOERSHEIM, M.D.,

NEW YORK.

Reports on the use of the suprarenal capsule in diseases of the upper air passages have been published by Joseph A. Mullen, H. L. Swain, Beaman Douglass, H. H. Curtis, W. H. Bates, S. Solis-Cohen, and others.

The diseases in which I have used the suprarenal powder are: acute tracheo-bronchitis, chronic bronchitis, bronchiectasis, congestion and œdema of the lungs, hæmoptysis, and pulmonary tuberculosis.

The suprarenal powder was always administered in the form of three-grain capsules, placed in the mouth, thoroughly chewed without water, and swallowed in a few moments. The action of the suprarenal powder administered in this way became apparent in three to ten minutes. The capsule of suprarenal powder should not be swallowed whole with water, because the juices of the stomach may destroy it.

Acute tracheo-bronchitis: In thirty-two cases the suprarenal powder lessened the frequency and severity of the cough. In some cases the cough entirely disappeared or remained absent from ten minutes to nine hours, according to the severity of the attack. The expectoration was decreased in amount, the mucous râles in the bronchi were diminished, and in those cases in which the attack was of a mild type, the râles entirely disappeared. The sensations of tightness, rawness, pulsation, and dryness in the upper portion of the chest and throat were more or less temporarily relieved. The respirations became easier, and the patients stated that they could expand their chests more fully than before the administration of the suprarenal powder.

When the suprarenal powder was administered at the onset of a bronchitis, three grains every one or two hours, with no other treatment, a cure was usually obtained in twenty-four hours. The acute rhinitis was also promptly relieved by the administration of the suprarenal powder.

Chronic bronchitis: Twelve cases of chronic bronchitis were temporarily relieved by the administration of the suprarenal powder. The benefit was apparent within fifteen minutes after the first dose.

Bronchiectasis: The expectoration when profuse was markedly diminished by the suprarenal powder. The cough was lessened, and the patients felt much relieved.

Bronchial asthma: When the paroxysms of asthma are due solely to nervous influences, the suprarenal powder has no power to control the attack. But if the attack is accompanied with hyperæmia of the bronchial mucous membrane, the suprarenal powder is usually beneficial.

Congestion of the lungs: When the suprarenal powder was administered the râles disappeared within fifteen minutes. The slight dulness over the posterior and lower portion of the lungs also disappeared. The slight cough and watery expectoration which were present in many of the cases were promptly checked. In a few the râles remained absent.

Œdema of the lungs: When the suprarenal powder was administered the râles markedly decreased in number, and the dulness became diminished with the rapid absorption of the fluid. It should be administered frequently. It may act in the same way here as it does in œdema of the nose, by relieving congestion.

Hæmoptysis: In sixteen cases of hæmoptysis from various causes, the suprarenal powder, chewed, stopped the bleeding from the lungs in less than half an hour. In six cases, the hemorrhage stopped in five minutes. The suprarenal powder was more efficient than other remedies employed. It was not objectionable in any way.

Pulmonary tuberculosis: In eight cases of pulmonary tuberculosis the expectoration and the cough were diminished by the suprarenal powder within fifteen minutes. The patients breathed more easily and felt brighter. Hæmoptysis, when present, was controlled. Some of the larger râles and many of the smaller ones disappeared.

The following are a few of the cases in which the suprarenal powder was administered:

Case I.—Mrs. L. S——, aged fifty-nine years, had a severe attack of acute bronchitis with profuse expectoration and a constant harassing cough. The suprarenal powder was administered with difficulty. In four minutes the cough was lessened in severity and the expectoration diminished in amount. Five minutes later gr. vi. more was administered, and in six minutes the cough had almost entirely disappeared. The hoarseness, rawness, and sensation of tightness around the neck and chest materially lessened. The action of the two doses of the suprarenal powder continued for about three hours.

Case II.—Mr. F——, aged twenty-four years, had a tracheo-bronchitis with acute rhinitis, with a short, frequent cough and a slight expectoration. Three grains of the suprarenal powder was administered, and in two minutes the nose opened, the cough and expectoration disappeared. The next day he developed a severe bronchitis from exposure, when gr. xviii. of suprarenal powder, in divided doses, were necessary to control the cough completely. The relief was permanent.

Case III.—Mrs. M. A——, aged thirty-seven years, developed a severe attack of acute bronchitis Suprarenal powder within two minutes lessened the cough and expectoration, and the patient felt better. The suprarenal powder was administered every two to three hours with benefit.

Case IV.—Mr. G. H——, aged twenty-nine years, had a severe attack of acute bronchitis with expectoration of a very thick, tenacious, yellowish mucus and a severe cough with marked hoarseness. Suprarenal powder, gr. vi., had no effect in ten minutes. At the end of that time gr. x. more was administered with apparently no benefit. Five-grain capsules of ammonium carbonate were ordered to be taken, one every two to three hours, and the patient to report when the expectoration became thin. The following day I ad-

ministered gr. vi. of suprarenal powder, and in six minutes the cough and expectoration became perceptibly lessened. At the end of fifteen minutes gr. ix. more were administered, and in twenty minutes the cough and expectoration had almost entirely ceased. His throat, which had felt hot and sore, was much relieved.

Case V.—Mrs. L. H——, aged forty-seven years, developed a severe attack of bronchitis following an extensive burn of the face, neck, chest, and right arm. Suprarenal powder was administered every hour. The cough was temporarily controlled.

Case VI.—Miss A——, aged fifteen years, had an attack of acute bronchitis. She was suffering from kyphosis, pulmonary tuberculosis, cardiac disease, anæmia, and rachitis. The suprarenal powder stimulated her diseased heart; the cough became lessened, the expectoration diminished in amount; the pain and rawness in the chest, which she experienced on inspiration, disappeared; the burning sensation in the throat lessened, and on inspection of the throat it was observed that it gradually became paler. Hæmoptysis, which was slight but constant for three days, was promptly checked.

Case VII.—Mr. P. K——, aged forty-eight years, had a severe attack of acute bronchitis on a chronic bronchitis with bronchial asthma. He expectorated three pints of mucus daily for two years. He was in a desperate condition: he was cyanotic; the heart was weak; the cough was extremely harassing with no intermission for two hours before I saw him. He seemed to be suffocating, and showed signs of impending heart failure. Six grains of suprarenal powder was administered with great difficulty on account of the constant coughing. In two minutes the cough became perceptibly lessened, and a change came over the patient, which indicated that marked relief was afforded. The respirations became fuller and easier, and the heart was stimulated. In five minutes the profuse expectoration and very severe cough had almost entirely disappeared, to the great surprise of the patient, his relatives, the neighbors, and myself. No such prompt and marked relief was afforded by any other treatment. The patient remarked that he had not felt so well in two years. The action of the suprarenal powder continued twenty minutes, when his symptoms began to return. A second dose gave prompt relief.

Conclusions.—1. Indications for suprarenal powder: The suprarenal powder is indicated in acute and chronic bronchitis, bronchiectasis, asthma, congestion and œdema of the lungs, hæmoptysis, and in some cases of pulmonary tuberculosis, especially in those associated with hæmoptysis.

2. Method of administration: The suprarenal powder was administered in the form of three-grain capsules on account of their convenience. The powder is to be chewed without water and then to be swallowed in a few moments.

3. Rapidity of the action of suprarenal powder: The action became apparent in from two to fifteen minutes.

4. Permanence of the action of suprarenal powder: In some cases the action of the suprarenal powder was permanent, while in the majority of cases the action was temporary, continuing from ten minutes to six hours.

218 East Forty-sixth Street.

Rigidity of the Spine.—J. H. McBride reports for the first time the histories of two cases seen some thirteen years ago. Case I. was that of a soldier who was not wounded in service, but whose spine some ten years later began to get stiff. The head was thrown forward and carried in that position apparently with the greatest care. The knees were bent in, apparently from contraction of the adductor muscles, while the hip joints were almost immovable. Early in the disease he had some pain in the left foot but that disappeared and otherwise he had no pain, spasms, or tremors. Later a curvature of the dorsal spine developed. Case II. was that of a laborer in whom the diagnosis of hypertrophic cervical pachymeningitis was made, the condition following trauma.—*Journal of Nervous and Mental Disease*, October, 1900.

The Diagnostic Value of Babinski's Sign.—J. Kollarits describes this phenomenon as being best elicited when the muscles of the lower extremities are relaxed, and the patient with closed eyes knows nothing of the experiment about to be performed. The thigh with the leg slightly flexed is to be supported by the observer's hand, and the sole of the foot gently irritated by pricking, tickling, etc. In normal adults the foot will be dorsi-flexed and the toes flexed toward the plantar surface, but if the sign be present, while the foot is flexed as before, the toes are extended. The significance of the phenomenon, according to its discoverer, is that it is present only, though not always, when the pyramidal tracts are diseased. A review of the literature leads Kollarits to believe that this is true, and that the symptom is of value in distinguishing organic from functional disorders. Furthermore, in apopletic cases it gives early information as to which side will be the paralyzed one.—*Klinisch-therapeutische Wochenschrift*, September 23, 1900.

Exclusive Soup Diet and Rectal Irrigations in Typhoid Fever.—Basing his statements upon a personal experience of one hundred and fifty-three cases in private and hospital practice during the last ten years, A. Siebert gives the following as the results of this mode of treatment: 1. Delirium, headache, insomnia, nausea, vomiting, and tympanites usually disappeared within forty-eight hours of treatment. 2. Tympanites, nausea, and vomiting never developed in any patient, even when complicating pneumonia was present. 3. The fur on the tongue disappeared within a few days. 4. Appetite came frequently on the fourth day of treatment, even when the thermometer registered 102° to 103° F. 5. Even excessive diarrhœa (fifteen to twenty-five daily stools) disappeared invariably within the first week of treatment. 6. In all uncomplicated cases the temperature began to decline within twenty-four to forty-eight hours after the beginning of treatment and invariably would reach the normal figure within ten to twelve days. 7. In cases complicated by pneumonia, nephritis, or phlebitis when treatment began, the temperature usually remained in accord with the inflammatory conditions found until these also disappeared; while the cerebral, gastric, and intestinal disturbances usually subsided as rapidly as in the uncomplicated cases, excepting anorexia. 8. Complications, when not present at the start, were very rare and then usually developed within the first two days. 9. Intestinal hemorrhage was noticed in three cases, none ending fatally. Perforation did not occur. Five feedings were given during the day. After an initial purge the patients seemed to do as well for forty-eight hours on cold water alone as on any kind of food. Then soups were given made of barley, oatmeal, rice, and peas, strained and well salted and peppered. Two days later lentil soup and the yolk of a fresh egg were added to the oatmeal, rice, and barley soups. An adult was allowed half a pint of two kinds of soup alternating, every three hours. Five to fifteen drops of dilute hydrochloric acid were given before each meal unless hyperacidity prevailed, but no other medicine. Cold water was allowed ad libitum.—*Northwestern Lancet*, October 1, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, November 17, 1900.

THE SYMPTOMATOLOGY AND TREATMENT OF PANCREATITIS.

THE difficulties surrounding the diagnosis of intra-abdominal disease are so well known as not to require elaboration. Nevertheless, a good deal of light has been thrown in recent years upon this subject, and among the affections to which considerable attention has been given are those of the pancreas. Like other tissues, this organ may be the seat of hemorrhage, of inflammation, of new growths, and its ducts of cystic dilatation and of calculi. A special feature of all forms of pancreatic disease may be the development of the condition known as fat necrosis. By reason of its relations with the intestine, the pancreas is peculiarly exposed to the dangers of infection, and through the junction of its excretory duct with that of the liver, disease of the one may give rise to symptoms also of disease of the other. An admirable description of pancreatitis is given by Mayo Robson (*Lancet*, July 28, 1900, p. 235) in a clinical lecture recently delivered before the Medical Graduates' College and Polyclinic of London. The acute disease, it was pointed out, may be hemorrhagic, suppurative, or gangrenous. It usually sets in with sudden pain in the superior abdominal region, attended with faintness or collapse and followed by vomiting. The bowels are almost always constipated, although flatus may escape and a large enema may secure an evacuation. Should the patient survive for a few days, diarrhœa may supervene. The pain undergoes paroxysmal exacerbations and is attended with tenderness above the umbilicus. It is soon followed by distention in the superior abdominal region, which may become general, and by vomiting, first of food and then of bile. Slight icterus is usually present, and becomes gradually more pronounced. The aspect is anxious and the face pinched. The pulse is rapid and small, while the temperature may be normal, subnormal, irregular, or high. Delirium may develop at a late stage. If careful examination can be made the pancreas may be found enlarged. Death usually occurs between the second and the fifth day from collapse, although in less acute cases life may be more prolonged.

In cases of subacute pancreatitis collapse is less marked and may be wanting; the upper abdominal region does not become so rapidly swollen, and vomiting is less severe and less prolonged. In other cases the onset is more gradual, though the symptoms may be similar. Tenderness over the pancreas is well marked, and it may be possible to feel the swollen gland, especially under an anæsthetic. Constipation gives place to diarrhœa, and pus or blood may appear in the stools, which may have a very fetid odor. The pulse is less rapid and less thready, and the temperature more irregular. Repeated rigors may occur. Constant dull epigastric pain is present, with paroxysmal exacerbations. The more urgent symptoms may subside and improvement appear to be taking place, but loss of flesh continues and relapses usually occur, leaving the patient each time more feeble, until death supervenes from asthenia. Albuminuria is pretty constant, but glycosuria is rarely present, and lipuria is an uncommon symptom. Should an abscess develop a tumor may appear in the superior abdominal region, or the pus may burrow into the loin and form a perirenal abscess, or under the diaphragm and form a subphrenic abscess; or it may follow the psoas muscle and form a subperitoneal abscess in the iliac region, or pass over the brim of the pelvis and collect in the left broad ligament. The abscess may rupture into the stomach and the pus be vomited, or into the bowel and the pus be voided through the anus. With the evacuation of the pus, temporary relief follows, but relapses usually occur and a mild form of septicæmia persists, with a hectic temperature. Death is the usual termination, although recovery may occur after a tedious and prolonged illness.

Chronic pancreatitis probably arises usually by extension from chronic catarrh of the pancreatic duct, secondary to gastro-duodenal catarrh, though it is frequently associated with biliary or pancreatic lithiasis, or with gastric, pyloric, or duodenal ulcer. Its onset may be gradual and painless, or attended with severe epigastric pain, followed by jaundice and associated with nausea and vomiting, and perhaps followed by a feeling of chilliness or even a rigor. A tender spot is usually present an inch above the umbilicus in the middle line. The jaundice tends to deepen with each attack until it becomes continuous and chronic, although it is not necessarily present at first. The pain may undergo paroxysmal exacerbations or consist merely in a dull ache, deeply seated, and burning and boring in character. A swelling of the pancreas can sometimes be made out, but usually only under anæsthesia. Loss of flesh and of strength are always well-marked symptoms. Vomiting may sometimes be absent, but the appetite is usually wanting, and flatulent dyspepsia is present, together always with a sense of fulness and weight at the epigastrium for some time after eating. The stools are white when the pancreatic fluid alone is absent from the intestines. Diarrhœa is often present and the intestinal discharges are offensive and fatty. Albuminuria is common and glycosuria may occur. Fever may be absent, although in some cases the temperature pursues a hectic course, especially when ague-like paroxysms occur. When jaundice is present the pulse may be slow, although it is not much accelerated even when the temperature is elevated, though it may be poor. In the later stages, especially if jaundice is present, hemorrhages from the

nose and the bowel, hæmatemesis, and petechiæ occur, and death results from progressive asthenia. In the more chronic cases, especially when there is contraction of the head of the pancreas, a tumor will be formed by the distended gall bladder.

Chronic interstitial pancreatitis is to be differentiated from gall stones in the common duct, from carcinoma of the head of the pancreas or of the liver and the bile ducts, and from chronic catarrh of the bile ducts. The disease may last for months or even years. The presence of glycosuria renders the outlook more grave. Increasing weakness and the supervention of hemorrhagic tendencies usually indicate the near approach ot a fatal termination. Under surgical treatment the prognosis is most favorable.

In the treatment of acute infective pancreatitis the pain at the outset is so acute as to necessitate the administration of morphine, and the collapse will probably demand the use of stimulants, which, on account of the associated vomiting, may have to be given by enema. In the early stages the symptoms are so indefinite that the indications for surgical treatment are not sufficiently clear to warrant operation, and no surgical procedure would be justifiable until the collapse has passed off. As prompt evacuation of the septic material is necessary for recovery, early exploration in the left costo-vertebral angle is demanded.

In the subacute form of pancreatitis morphine may be required to relieve the paroxysmal pain, and stimulants and food by the rectum to relieve the collapse and sustain the strength. Distention may require relief by lavage of the stomach and turpentine enemata, or by the administration of calomel by the mouth in small, repeated doses, or in doses of five grains, followed by an aperient. Should diarrhœa supervene, salol and bismuth, with small doses of opium, may be given. Should surgical treatment be decided upon, a median incision above the umbilicus will enable the operator to palpate the pancreas and locate any incipient collection of pus, which should if possible be evacuated by a posterior incision in the left or right costo-vertebral angle, or, failing that possibility, the collection of pus may be aspirated, and the cavity opened and packed with gauze, which may be brought forward through a large rubber drainage-tube that will in the course of from twenty-four to forty-eight hours establish a track isolated from the general peritoneal cavity. Should a definite abscess form and approach the surface in front or in either loin, incision and drainage will be demanded. The strength must be maintained by careful feeding and the judicious administration of stimulants. Further collections of pus and subphrenic abscess or empyema will require special treatment.

In cases of chronic interstitial pancreatitis, manipulation of the indurated tumor may detach calculi impacted in the duct, while in others the relief of tension, as the result of draining the bile ducts by cholecystotomy or cholecystenterostomy, may indirectly drain the pancreatic duct and thus lead to a subsidence of the pancreatitis, then to an opening of the common duct by the relief of the tension, and so to cure. The simulation of malignant disease of the head of the pancreas by chronic interstitial pancreatitis should make the surgeon hesitate to decline operation in any case of distended gall bladder when the patient is in a condition to bear it, or even in any case of chronic jaundice without distention of the gall bladder when the general health is deteriorating; for although if the disease be malignant little good can be done, yet if the disease prove to be chronic pancreatitis real and permanent cure may be brought about. If a calculus be felt embedded in the head of the pancreas or impacted in the pancreatic duct, it may be reached through the second part of the duodenum by laying open the papilla and exploring the duct, or by dividing the peritoneum passing between the duodenum and the hepatic flexure of the colon, and then cutting through the overlying pancreas on the concretion. If the papilla be incised it does not require suture, and exploration of the ducts by the duodenal route may be unattended with hemorrhage. The anterior duodenal opening requires closing by a mucous and a serous suture. Drainage of the right kidney pouch for from twenty-four to forty-eight hours is advisable, although not always necessary, and this is best secured by means of a stab wound at the most dependent part. For attacking the head of the pancreas or the pancreatic duct a vertical incision should be made through the right rectus and not in the middle line. In cases presenting deep jaundice, it is well to prescribe calcium chloride in twenty-grain doses thrice daily for twenty-four or forty-eight hours before operation, and to give it in an enema form for twenty-four hours afterward in sixty-grain doses thrice daily. Of seventeen cases operated on in which chronic pancreatitis was found, recovery ensued in sixteen.

CAUSES OF SUICIDE.

Dr. J. W. C. Cuddy, professor of medicine in the University School of Medicine, Baltimore, contributed to *The Baltimore American* an able article on the subject of suicide. He is of the opinion, which is probably shared by most scientific men, that no absolutely sane person takes his own life. In those cases in which an individual commits suicide there is undoubtedly an unhinging of the mental balance. This may be temporary, but nevertheless self-destruction must be attributed to an insane impulse. There are many, however, of course, who do not hold this view, but believe that suicide may be a deliberate sane act. Dr. Cuddy writes as follows on the matter: "There are very few direct causes of suicide, and these are the very ones which will most readily disarrange the harmonious workings of a healthy mind. The most frequent causes of self-destruction to which I allude can best be told by a quotation from one of my own lectures to the medical class during the last session. In that lecture I said: 'The main exciting causes of suicide are financial depression, religious mania, and unrequited love. The first mentioned are generally male adults, who, as a rule, complete their sad taking off by the help of the leaden ball or glistening steel; the unbalanced religionist generally seeks some secluded spot, where with hempen cord he chokes out

the God-given life which should have been used for a better purpose; while it remains for lovesick maidens and half-crazed men to terminate their useless existence by the aid of some poisonous drug, nearly always the same, for the intelligence of such persons rarely leads them beyond the laudanum bottle of the household, in whose somnolent depths they seek their voluntary oblivion.' Now these three causes which cover the majority of cases of suicide are all producing agencies of deranged nerve action, and it is but natural to conclude that in these instances the brain cells are sufficiently disorganized to produce a condition whereby normal or mental control is lost prior to the consummation of the suicidal act. The question might be asked, Why do not these operative causes act alike in all similar cases? All brains are not constituted nor developed alike. Some are able to resist the most distressing and depressing agents, just as some bodies will exist in a bacteria-laden atmosphere and escape unscathed, while others similarly placed will readily succumb, even to fatal results."

Dr. Cuddy also mentions heredity as perhaps a predisposing cause, but fails to draw attention to one of the most potent causes of suicide—alcoholism. There can be no doubt whatever that strong drink drives a vast number of human beings to death by their own hands. It would, of course, be extremely difficult, probably impossible, to tabulate definitely in their correct order the various causes of suicide. The majority of observers would haply declare both religion and the lack of religion to be responsible for more suicides than any other one cause, but few will deny that to excessive drinking is due directly and indirectly a holocaust of victims.

SANATORIUM FOR CONSUMPTIVES IN ENGLAND.

Liverpool is one of the most progressive towns in Great Britain. The good work she has done in furthering and extending the knowledge of tropical diseases among the medical profession of her country is well known. Through the efforts of Liverpool philanthropists the first public sanatorium for the open-air treatment of consumption has been commenced. This establishment will be in connection with the Liverpool Hospital for consumption, and is to be erected in a healthy locality near the sea-coast at a convenient distance from the town. The building is to be essentially for use rather than for ornament. The main structure will consist of three blocks, the largest of which will be chiefly devoted to dining-accommodation. The peculiar feature of the dining-hall will be that it has a roof only and no sides. Around this main building a number of small bungalows are to be constructed, each to contain six bedrooms, and nothing more. No accommodation will be provided for the patients other than bedrooms and a dining-room, so that when not eating or sleeping they will be living in the fresh air. The erection of a sanatorium on these lines is decidedly a movement in the right direction. The organized adoption of the open-air treatment of consumption has in Great Britain, and in a lesser degree in this country, lagged somewhat. In Great Britain especially, old views die hard and prejudice is difficult to overcome. In Germany, and in some other parts of the world, the new method has had gratifying success. Probably a want of knowledge among the general public is the greatest barrier of progress. There are undoubtedly many persons who would regard with distrust the suggestion that the tuberculous patient should be out in the open even in the winter, and there are assuredly some who would esteem such a mode of treatment as emanating from the brain of a madman. The chief requirements of a person suffering from phthisis in any stage are air and light, and further than this it is undoubtedly possible in the early stages by these means to effect a cure. For the popular ignorance on the question of the treatment of tuberculosis the medical profession itself is largely responsible, having up to a comparatively recent period taught and practised a different system. If its members will assist strenuously by precept and practice in illuminating the public mind on the subject, they will be acting for the good of everybody. Dirt, dust, and darkness are the greatest propagators of tuberculosis, and until this fact receives a widespread appreciation, then, and not till then, will there be a fair likelihood of the spread of the disease being checked.

News of the Week.

Dr. Pozzi's Duel.—Dr. Devillers, who some time ago wantonly insulted Dr. Pozzi in his club, and forced him to fight a duel, has had to pay for it in the courts. The government, in spite of Dr. Pozzi's protests, instituted proceedings against Devillers for assaulting a member of the French Senate, and the court condemned him to pay a fine of 3,000 francs.

The Russian Red Cross Society.—The Russian government, for the second time within two months, has imposed a special tax for the benefit of the Red Cross Society. The first was a tax of from 5 to 10 rubles upon licenses to travel abroad, according to the length of time for which the license was granted; and now railway tickets are taxed 5 kopecks when the fare is 2 rubles or upward. It is estimated that the ticket tax will yield $125,000 yearly, and that on licenses $100,000. It is understood that the Czarina, whose interest in the Red Cross Society is keen, originated the idea of imposing the taxes.

Disinfection of Lepers' Mail.—The following plan for disinfecting the mails from the leper settlement at Molokai has been instituted by Dr. Carmichael of the Marine-Hospital service at Honolulu. All mail from the leper settlement will be disinfected with sulphur dioxide at the settlement and then transferred directly to the steamship and received aboard in clean and disinfected sacks furnished by the post-office authorities. At Honolulu the mail will be taken in the sacks directly to a room in the post-office used for disinfection purposes and disinfected with formaldehyde with-

out removal from the sacks. All letters are perforated or the corners clipped at the settlement before disinfection. No case of leprosy, the surgeon reports, has yet been discovered among the post-office employees, although non-disinfected mail from the leper settlement has been handled by them for many years.

Crowd Injuries.—Sixteen hundred persons suffered injuries requiring medical attendance in the crowds that assembled in London on Monday of last week to welcome home the volunteers from South Africa.

The Cost of the Plague in Glasgow.—According to a despatch from Glasgow the estimated cost to that city of the recent visitation of the bubonic plague was £1,000,000 ($5,000,000).

Yellow Fever in Mississippi?—A case of supposed yellow fever has been reported to the Mississippi State board of health from Natchez, the patient having died last week. A Marine-Hospital surgeon has been sent to that city to trace, if possible, the source of infection.

Smallpox in Paris.—It is reported in *The Sun* that an epidemic of smallpox has broken out in Paris, due probably to the massing there of Arabs and other people from the East during the Exhibition. Notices have been posted by the police warning persons who have not been vaccinated within six years to be vaccinated now. Every precaution to stamp out the disease has been taken.

Rabies in New York.—A fox terrier was killed in this city a short time ago, after it had bitten other dogs and a boy, and examination by the bacteriological department of the board of health confirmed the diagnosis of rabies. The board of health has issued a statement calling "the attention of physicians and others to the occurrence of a number of cases of rabies among dogs throughout the city, and would request that wherever persons are bitten by strange dogs, or stray dogs, they immediately consult a physician and have their wounds cauterized, and if then there is any question as to the existence of rabies in the animal, communicate at once with the department of health."

The Civil Rights of Hospital Internes.—The case of the Bellevue Hospital interne and four male nurses, who were arrested on the charge of having illegally registered, has been decided in their favor by Justice Andrews. The cases were in the nature of test cases, and as a result of the decision five hundred and fifty-six internes and helpers in Bellevue and other city institutions, whose status was in doubt, were allowed to vote. The law which forbids the pauper inmates of city institutions to vote was the basis of the charge against them, but the court said that "it cannot be truthfully said that the physicians, hired helpers, or pupil nurses are supported by the public. The physicians render most valuable services to the patients in the hospital and are allowed to lodge and eat there, not as a matter of charity, but as a matter of convenience and almost of necessity, owing to the nature of the duties which they are at all times called on to perform."

A Tax on Childless Frenchmen.—A bill has been introduced into the French Senate providing for a tax on celibates of both sexes after they reach the age of thirty, and upon childless couples who have been married for five years, the tax to be maintained until a child is born to them. The aim of the bill is, of course, to provide a remedy for the threatening depopulation of France, by increasing the birth rate.

A Death Under Chloroform.—A boy nine years old, who was being anæsthetized preliminary to an operation for injury to the thigh, died last week at the New York Polyclinic Hospital. Chloroform was the anæsthetic employed, and the boy died soon after the inhalation was begun.

Excessive Mortality among the Alaska Indians.—Officers of the United States revenue cutter *Rush* report that the Indians of the Aleutian Islands, as well as those of the Alaskan peninsula and on the mainland, are dying at an alarming rate. The *Rush* was engaged during the summer in Indian census enumeration. Attu Island, in past years densely populated with Alaskan natives, contains only seventy-three, and Atka, the largest island of the group, has an Indian population of but one hundred and seventy-five. That island half a century ago supported a great tribe. Last season measles and pneumonia carried off the Indians by the score, and should these diseases become epidemic again next year the archipelago will become almost depopulated.

Yellow Fever in Havana is decreasing. In a report recently presented to the Washington authorities, Dr. A. H. Glennan, of the Marine-Hospital service, now chief quarantine officer for the island of Cuba, says that the number of cases decreased in the last week of October, and that there were only thirteen deaths in that week. He quotes with approval the assertion of Dr. W. C. Gorgas, of the United States army, now chief sanitary officer of Havana, that, notwithstanding the general distribution of the disease, infecting localities not heretofore infected, and the large number of people attacked, an epidemic condition does not exist, and that such a situation in Havana is impossible. He says that from June 1st to October 19th there were seven hundred and eighty-nine cases officially recorded; that the official maps of the city show that there are eight hundred and fifty-seven square blocks in the city, and that of this number five hundred and twenty-five square blocks have had no cases at all. In any ordinary acceptation of the word epidemic as applied to diseases in great cities, Major Gorgas says, this certainly does not show that there is an epidemic there. In a population of two hundred and thirty-two thousand the average during October, which has been the largest of the year, has been ten new cases a day. In September there were seventy-two deaths from consumption, fifty-two from yellow fever, and forty-three from enteritis. Yellow fever, therefore, should not be considered epidemic any more than consumption or enteritis. It has been decided that hereafter the steamboat companies will meet the Spanish transatlantic liners outside of Havana harbor

and will transfer immigrants destined for other points. Those going to the rural districts of the provinces of Havana and Pinar del Rio will be sent to the Cabanas Barracks, and will not be allowed to remain in Havana. It is thought that these precautions will result in a rapid decrease of the yellow fever, as ninety per cent. of the cases now under treatment are among the immigrants.

Trial of an Emergency Ration.—A board of army officers is making a test of the efficiency of three different emergency rations. Two of these rations are offered by manufacturers and the third is one proposed by the board itself. This is composed of two cakes of sweetened chocolate and three cakes of a meat-and-cereal compound. The chocolate weighs four ounces and the meat and cereal in combination respectively four and eight ounces, a total weight of sixteen ounces, besides three-fourths of an ounce of salt and one gram of red pepper. The ration is contained in a hermetically sealed can with rounded edges like a flask, six and one-fourth inches long and one and one-half by two inches. The can is opened with a key. The ration is to be part of the permanent equipment of the soldier in the field. It can be eaten dry; as a soup or a porridge, or the porridge may be fried. The question to be decided is whether the ration has sufficient quantity and quality, and will not nauseate when used alone. The first test was made about two weeks ago in Oklahoma. The detachment of troops started from El Reno, and marched across the Indian reservations of the Kiowas, Comanches, and Apaches to Fort Sill. During the march the men lived wholly upon the emergency ration. The food went hard with the men for the first few days, but after that time they seemed to enjoy it.

The Distinction between Anopheles and Culex.—Major Donald Ross and Mr. A. E. Austen in the report of their expedition to Sierra Leone in 1899 laid great stress on the position assumed by mosquitos when at rest, as a means of discriminating between the malaria-bearing mosquitos of the genus Anopheles and those of the genus Culex, the latter of which so far seem to take no part in the dissemination of human malaria. They said that the Anopheles always, when at rest, sat in a characteristic attitude, their bodies being maintained at an angle of at least 45° to the surface on which they settled. Frequently, they said, the tips of the palpi were in contact with the wall on which the insect was resting, and the body was so much elevated that it was practically at right angles to the wall, the insect appearing as if it were standing upon its head; and it was held that, owing to this extremely characteristic resting attitude of Anopheles, it would be impossible for any one who had once seen a specimen at rest to mistake it for a Culex, for the latter when at rest allows its body to hang down vertically. Now Dr. Sambon and Dr. Low have been passing the summer on the Campagna, and they directly traverse this statement as to the attitude of these insects. They say that they have observed thousands of Anopheles, but none of them ever assumed the position described by the members of the Liverpool Malarial Mission, and they hold that although the resting position may be a means of distinguishing between certain species, it is not a criterion by which Anopheles can be distinguished from Culex which was the point insisted on, a point which has already been copied into many text-books.—*The Hospital.*

The Comparative Cost of a Medical Education.—In a recent article in the London *Daily Mail* a comparison was made of the cost of education in the different professions. It was asserted that, on the average, it cost the student about £950 to qualify as a physician; £800 to become a lawyer; £775 to enter the church; £600 to become an officer in the army; and £400 for an officer in the navy.

College of Physicians of Philadelphia.—At a stated meeting held November 7, 1900, Dr. Charles W. Burr read a paper, prepared by himself and Dr. D. J. McCarthy, entitled "Asthenic Bulbar Palsy," reporting a fatal case in which only diminution in the size of the pons was found after death, without histological alteration, and a second case in which the symptoms disappeared and recovery ensued. Dr. John B. Deaver read a paper entitled "Appendicitis versus Cystitis," reporting several illustrative cases. He emphasized the significance of pain in the left iliac fossa as indicative of appendicitis with pelvic involvement. Dr. W. Joseph Hearn read "A Report of a Case of Resection of a Large Portion of the Ilium for Chondro-Sarcoma." Dr. W. W. Keen described a method of transplantation of the tissues in one mammary region to the opposite side to replace structures removed in the treatment of recurrent malignant disease of the breast.

Pathological Society of Philadelphia.—At a stated meeting held November 8th, Dr. William L. Coplin exhibited (1) an improved mechanical stage for Dölken's microscope; (2) an improved drawing ocular; (3) a revolver for securing parfocal adjustment. Dr. M. P. Ravenel presented a communication entitled "A Possible Source of Infection in Tuberculosis," in which he detailed observations demonstrating the possibility of the conveyance of tubercle bacilli with the particles of mucus expelled by cows in the act of coughing. Dr. Joseph McFarland reported a case of deciduoma malignum, which seven years ago had been clinically considered one of sarcoma of the uterus, and on histological examination presented appearances suggestive of endothelioma. Dr. McFarland also exhibited the Blake-Minot microtome, with which small sections of soft tissue embedded in paraffin can be cut as thin as 1 μ. Dr. A. E. Woldert exhibited specimens of the middle intestine of the Anopheles quadrimaculata, containing the xygates of the Proteosoma Labbé, loaned by Surgeon-Major Ronald Ross, of the Liverpool Tropical School of Medicine. Dr. Woldert also reported a case of malarial hæmoglobinuria, and exhibited the malarial parasites obtained from this source. Dr. M. B. Hartzell presented a communication entitled "Note Relative to the Parts of the Skin Invaded by the Microsporon furfur in

Tinea Versicolor, with Illustrations." He showed that the invasion of the parasite was not confined to the horny layer of the skin, but at times invaded also the hair follicles. Dr. A. O. J. Kelly exhibited specimens of abscess of an hypertrophied prostate, greatly thickened, contracted, and ulcerated bladder, diphtheroid inflammation of the large and small intestines, and inflammation of the kidneys. Dr. W. M. L. Coplin exhibited a specimen of ulceration of the œsophagus into the trachea and the posterior mediastinum of as yet undetermined origin. Dr. W. G. Spiller exhibited specimens illustrating Mallory's new neuroglia stain.

Modern Bullet Wounds.—Surgeon-General Sternberg in his annual report has much to say regarding the effect of gunshot wounds made by rifles of reduced calibre. A review of the statistics shows that the percentage of fatality during the Spanish-American War, in which small-calibre projectiles were used, was much lower than in the Civil War, when extremely large bullets were used. Rapid healing follows wounds made by the Mauser bullet, and infection was seldom noted, but when present was almost invariably about the wound of exit and consisted of a slight slough and a drop or two of pus under a scab. Among the fourteen hundred wounded none died of external hemorrhage, and it was not necessary to ligate a vessel for alarming hemorrhage on the field. Clean-cut perforations without fracture were the rule in wounds of the principal joints. A majority of gunshot wounds in the head ended fatally. Penetrating wounds of the abdomen were fatal in most cases. Owing to the smallness of the sectional area of modern bullets, pieces of clothing and other infectious material are not generally carried into the wound.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the navy for the two weeks ending November 8, 1900. October 29th.—Surgeon A. M. D. McCormick commissioned surgeon from November 11, 1899. October 30th.—Assistant Surgeon R. E. Ledbetter ordered to the *Constellation*. October 31st.—Surgeon C. Biddle detached from the *Texas* when put out of commission, and ordered home to wait orders. November 1st.—Medical Director C. H. White detached from the naval museum of hygiene, Washington, on reporting of relief, and ordered home to wait orders. Medical Inspector G. P. Bradley ordered to duty in charge of the naval museum of hygiene, Washington, November 15th. Surgeon H. E. Ames detached from the *Kearsarge* and ordered to the *Massachusetts*. November 3d.—Medical Inspector J. C. Boyd detached from the *New York* when out of commission, and ordered to the *Kearsarge*. Passed Assistant Surgeon E. S. Bogert, Jr., detached from the *New York* when out of commission, and ordered to the *Massachusetts*. Passed Assistant Surgeon M. S. Elliott detached from naval station, Port Royal, and to duty on the *Annapolis* when placed in commission. Assistant Surgeon W. M. Garton detached from the *Massachusetts* and ordered to the *Indiana*. November 5th.—Assistant Surgeon J. St. J. Butler appointed assistant surgeon from October 26, 1900. Passed Assistant Surgeon J. M. Moore ordered to naval station, Port Royal. November 8th.—Passed Assistant Surgeon E. M. Shipp detached from Norfolk hospital and ordered to the *Michigan*. Passed Assistant Surgeon H. D. Wilson detached from the *Michigan* and ordered to naval hospital, Norfolk, Va. Passed Assistant Surgeon L. W. Spratling detached from Yokohama hospital, and ordered to naval station, Cavite, Philippine Islands. Pharmacist S. Douglass ordered to additional duty on the *Massasoit*.

Obituary.

HENRY DRURY NOYES, M.D.,

NEW YORK.

Dr. Henry D. Noyes died at his summer home in Mount Washington, Mass., on November 12th, at the age of sixty-eight years. The cause of his death was pneumonia. He was born in this city and was educated at the New York University, from which he was graduated with the degree of A.B. in 1851. He was graduated in medicine from the College of Physicians and Surgeons in the class of 1855, and after serving on the house staff of the New York Hospital went abroad to continue his studies. Upon returning to this city he entered upon a special practice in diseases of the eye and ear, in which he achieved great distinction. His contributions to periodical medical literature were numerous and valuable, and he also published a treatise on the diseases of the eye. He was among the first to recognize the immense importance of cocaine as a local anæsthetic in operations upon the eye, and his letters on this subject to the Medical Record went far to establish the value of Koller's discovery and to popularize it in this country. He was for many years professor of ophthalmology and otology in the Bellevue Hospital Medical College, and was also executive surgeon to the New York Eye and Ear Infirmary. He was a member of numerous special and general medical societies and social organizations. A widow and three children survive him.

Dr. Noyes was the type of the progressive specialist, as during his whole professional life he adhered strictly and solely to perfecting himself in his particular branch of work. Combining the rare qualities of skill, sound judgment, and broad conservatism, he was ever a sound counsellor and one always to be trusted in the management of the gravest and most responsible cases. Having a finished and terse literary style, and being an eloquent and forcible speaker, he always impressed his colleagues as a born leader and a clear thinker. To the very last he was active in his work as a teacher, writer, and lecturer, proving that a sound constitution, a clear brain, and a steady hand are the legitimate rewards of a well-ordered and consistent life.

Obituary Notes.—Dr. Salome Merritt, a well-known advocate of woman's rights, died on November 7th at her home in Somerville, Mass. She was born at Templeton, Mass., on February 22, 1843. In 1871 she took up the study of medicine in the New England Female Medical College (now Boston University). Later she came to New York and was graduated in 1874 from the New York Free Medical College for Women, an institution which flourished for six years only. She began to practise medicine in 1876 and followed it as a profession since. She was a charter member of the Woman's Suffrage Association of Mas-

sachusetts, and was elected its president in 1893 and the four years following. She was president of the Ladies' Physiological Institution, and also served on the Committee of Counsel and Co-operation, a union of several Boston societies, whose aim it was to encourage moral reform, improved sanitation and dwellings for the poor, and other branches of benevolent work.

Dr. Nathaniel P. Rice, a retired physician of this city, died on November 10th, following a cerebral hemorrhage which occurred last summer. He was born in Cambridge, Mass., seventy-two years ago. After attending the public schools he went to Harvard, where he was graduated in the class of '49. He received his degree in medicine at the Harvard Medical School. At the outbreak of the Civil War Dr. Rice joined the New York volunteers, and two years later became a surgeon in the regular army, serving with the Army of the Potomac. He was medical director in Virginia and North Carolina in 1864–65.

Dr. J. S. Walters died at Pittsburg, Pa., on November 8th, at the age of fifty-four years. He was born in Chede, Staffordshire, England, and was a graduate of Guy's Hospital, London.

Progress of Medical Science.

Medical News, November 10, 1900.

The Examination of Stomach Contents. — B. A. Bastedo states that the simplest and best test-meal consists of a good-sized hard breakfast roll without butter, taken on an empty stomach. The roll should be thoroughly chewed and washed down with twelve ounces of water. At the end of an hour a stomach-tube is passed. If fermentation is present there is a layer of foam on the surface and there is an odor of butyric and other fatty acids. Mucus may be noted by lifting it up on a loop of wire. Of the filtered contents, 5 c.c. is placed in a porcelain dish with a drop or two of one-half of one per cent. alcoholic solution of dimethyl-amido-azo-benzol. If this becomes pink, it indicates the presence of free hydrochloric acid. The Congo-red test may then be tried. If blood is suspected, it may be tested for by adding glacial acetic acid and then ether to a bit of the stomach contents. The mixture should be shaken, set aside, and the ether poured off. To this ether should be added a few drops of tincture of guaiac and then a like amount of peroxide of hydrogen. A dark-blue color indicates blood. The writer then indicates the proper diet for various conditions of abnormal acidity. A suspected ulcer contraindicates the use of the stomach-tube, in which case the vomitus may give valuable information.

Bronchial Disease Not Invariably a Contraindication for Ether Anæsthesia in Abdominal Surgery.—Thaddeus A. Reamy declares that he believes that in properly selected cases ether inhalation is positively curative of bronchitis. Its action in these cases is probably largely local. He enumerates the following points which are essential to avoid unpleasant complications and to secure desired results: (1) Proper preparation of the patient; (2) preparation of the operating-room with a temperature of 98° to 100° F.; (3) pure ether; (4) a proper inhaler; (5) the proper methods of administration; (6) due caution against exposure in removing the patient from the operating-room to her own room, which should not be below 80° to 90° F. for several hours after the operation; (7) proper care of the patient during convalescence. She should be permitted to drink large quantities of water and should keep the bowels freely open.

Further Experience with Subarachnoidean Injections of Cocaine for Analgesia in All Operations below the Diaphragm.—By John B. Murphy.

Some Observations on Anæsthesia by Intraspinal Injections of Cocaine.—By S. Ormond Goldan.

The Hydriatric Treatment of Tuberculosis.—By J. H. Kellogg.

New York Medical Journal, November 10, 1900.

Facial Neuritis Associated with Unilateral Retro-Orbital Neuritis.—Report of case by W. M. Leszynsky. The patient was a woman aged thirty-eight years, who five weeks previously, after severe pain and tinnitus in the left ear (referred to exposure to cold) noticed that the left side of her face was paralyzed. Examination showed complete left facial paralysis with lagophthalmos, and loss of faradic irritability in nerves and muscles. The muscles reacted to galvanism AnCC < CaCC. Sense of taste was impaired on the left anterior two-thirds of the tongue. There was loss of taste for sweet, sour, and salt, but bitter could be distinguished. The palate, tongue, and pupils were normal. Chronic catarrhal otitis affected both ears. There were no physical signs of pulmonary disease, and no evidence of syphilis. The usual galvanic treatment of the facial muscles was instituted. By December 15th (in two months) she was able to close the left eye. On the 20th she began to complain of severe pain in the left temporal region and also over the supraorbital-nerve distribution, with tenderness on pressure and inability to sleep on account of the pain. There was no fever, but, the bowels being constipated, she was given gr. v. of calomel and gr. xx. of compound jalap powder. One week after the beginning of the pain, vision began to fail in the left eye, and two days later the eye was totally blind. The pain disappeared entirely at the end of the second week. The right eye was not involved. The left pupil was larger than the right. L. 5; R. 4. In the left there was no reaction to light, consensual, +, in convergence normal. Right pupil: no consensual reaction, but otherwise normal. There was no perception of light in the affected eye, while the right eye showed vision of $\frac{20}{15}$. At first there was slight œdema of the papilla, with blurring of outline on the nasal side of the disc. This gradually increased, and at the end of a week the papillitis was quite pronounced. The patient improved under the iodide and mercurial inunctions. Ten months later, vision was $\frac{20}{200}$; the ophthalmoscope showed optic atrophy. One year from the last-named date the following note was made: Although the nerve and muscles react to faradism 28 mm. (quantitative decrease in irritability), there is no improvement in the motility of the facial muscles. Optic-nerve atrophy is well advanced, and the vision of the affected eye is limited to perception of light, while the pupillary condition has remained unchanged.

An Unusual Case of Meralgia Paræsthetica, with Intermittent Lameness (Claudication Intermittente—Type Charcot).—By A. Gordon. The patient was a man aged forty-five years. The symptoms developed during typhoid fever. The disease mentioned in the title is due to some pathological or functional alteration of the external cutaneous nerve or a branch of the lumbar plexus. Whether the patient was sitting or walking he complained of a burning sensation over the antero-external surface of the upper two-thirds of the thigh, from the anterior spinous process down and over the posterior surface of the upper third, from the crest of the ilium down, covering the external surface of the buttock. Only on the upper third of the thigh did the area of disturbed sensation pass over the middle line. There it reached the internal surface of the limb as far as contact with the scrotum. The area bounded by the above outlines was not universally affected. Tactile sensation was much diminished. Pinching and rubbing were extremely painful. Thermic sensations were normal, but the temperature of the affected side was lower than that of its opposite. The mechanical and quantitative electrical reactions were exaggerated, but the qualitative was normal. The distribution of the paræsthesia was somewhat irregular. The author says that if the syndrome meralgia paræsthetica is the result of some functional or pathological change in the external cutaneous nerve, there are, nevertheless, cases in which the same symptoms, pain and paræsthesia, go beyond the zone of distribution of that nerve; also there are some, if not the majority, in which only one branch of it is affected, some in which other phenomena are associated with it, and, finally, some so-called pseudo-meralgias, in which the underlying cause is not in that nerve.

Ruptured Urethra, with Report of Cases.—N. Jacobson reports four instances under the following case headings: Subcutaneous rupture, external urethrotomy, faulty dilatation, subsequent divulsion, recovery; complete severance of the urethra subcutaneously, perineal section, perineal drainage, recovery; urinary fistula following urethral rupture, perineal section, recovery; penetration of the branch of a tree through the anterior wall of the rectum, severing the urethra completely, recovery. In general, diagnosis is made from urethral hemorrhage with retention of urine, associated with bleeding into the perineum, scrotum, and buttocks. Repeated introduction of a catheter into the bladder is not wise, and the wearing of a permanent catheter is not advisable. Jacobson believes that careful exploration with the finger will often enable us to locate the proximal end of the severed urethra.

A Case of Congenital Ocular Defect.—By E. E. Blaauw. The patient was a young woman aged twenty years, who complained of headache. On examining her eyes he found vision in each eye $\frac{5}{6}$; vision in both eyes together with + 0.5 D. $\frac{5}{5}$. With the Javal-Schiötz ophthalmometer a conical

astigmatism of ± 1 D., max. 0° (1). In the right eye fine opacities in the vitreous. When asked to follow an object with her left eye, she appeared absolutely incapable of so doing in the temporal part of the visual field, all abductive power of that eye seemed absent. She did not squint, never saw double images, and carried the head in a normal manner. By bringing a prism with its base horizontally before one eye she saw two homonymous images, especially after coloring the one, but not often was one image perceived.

Journal of the American Medical Ass'n, Nov. 10, 1900.

Rötheln: its Differentiation from Measles or Scarlet Fever.—Henry Koplik believes that rötheln is a distinct and definite disease, independent of measles or scarlet fever. The best authorities agree that the exanthema of rötheln appears first on the face. After remaining in full efflorescence on the face and trunk only from a few hours to a day, the rash begins to fade, and the patient may in the next twenty-four hours present a perfectly normal skin. The writer has never seen the pigmented spots seen in true measles. The buccal mucous membrane is the crucial test in diagnosis. In no case of true rötheln has the writer seen the rose-red spots with the bluish-white speck in the centre seen in measles. The buccal mucous membrane in most cases of rötheln is of a normal pale-pink hue. The temperature in this disease is highest at the outset of the disease when the eruption has appeared on the face. The writer has observed enlargement of the lymph nodes behind the sterno-mastoid muscle. Generally, the tonsils are enlarged. In varicella the spleen is sometimes palpably enlarged, but not in rötheln. Scarlet fever does not affect the face so distinctly, and on the trunk scarlet fever shows the acute dermatitis as a background for the punctate character of the general eruption. These punctate spots in scarlet fever have no particular arrangement; in rötheln, if the papules are as small as those of scarlet fever the skin between the papules has a normal color. The exanthema of measles of the discrete type closely resembles that of rötheln. Then the buccal mucous membrane is the crucial test. The highest temperature never goes beyond 103° F. The general condition of a patient is that of a person suffering a slight malaise. It requires little or no treatment. Children should be kept indoors till all signs of the exanthema have disappeared.

Measles and the Exanthemata: Shall Children be Kept Therefrom? Likewise from Diphtheria and Pertussis.—C. F. Wahrer does not believe that it is always best to keep children from acquiring measles, at least not with as good a reason as we have for preventing their acquiring such virulent diseases as scarlatina, variola, or diphtheria. As to rötheln and varicella, neither is ever fatal. Scarlatina not only kills thousands of children, but is followed frequently by serious sequelæ. It is not apt to be acquired by adults. As to diphtheria, what has been said of scarlatina is largely true of it. Variola is always a dangerous, loathsome malady with a large mortality. Pertussis is in early life very fatal and frequently attended by serious complications. Although adult life is not entirely exempt from it, still it is not so easily affected. The mortality from measles is great, but mostly during adult life. Its most dreaded complications and sequelæ are principally met with in adult life. Measles, ever so mild, is a prophylactic against any future exposure. There is a very light mortality among children under the age of fourteen years. The writer believes the disease should always be quarantined against in children's hospitals, in private schools, in severe winters, and in the unsanitary districts of crowded tenements. But when children in ordinary health can be exposed to a mild epidemic of measles, there would probably be as much benefit as when cowpox is substituted for smallpox. Adults are just as liable to acquire measles as children, and when acquired the disease usually becomes more dangerous. Till the diagnosis is established, it is best not to allow patients to come in contact with others.

A Clinical and Pathological Study of the Rash of Scarlet Fever.—The following inferences are drawn by Jay F. Schamberg: (1) The color of the rash in scarlatina varies in different individuals, and at different times in the same individual. Accurately speaking, it is never scarlet and only occasionally bright red. More commonly it is a dull red with an appreciable element of brown. (2) There are other elements of the eruption of scarlet fever besides the erythema, namely, puncta, vesicles, and goose-flesh papules, and these lesions occur with a considerable degree of constancy. (3) Vesicles are far more common in the rash of scarlet fever than is ordinarily believed. They are more profuse in intense eruptions, although they may be present in mild ones. The amount of desquamation is as a rule proportionate to the degree of vesiculation. Vesiculation may be so copious as to deceive the physician in his diagnosis. (4) Desquamation on the body begins as pin-point, powdery scales at the summits of the desiccated vesicles. Irregular or jagged rings of desquamation then form, which enlarge until the horny layer is completely shed. (5) Histologically, the rash of scarlet fever is a dermatitis exhibiting deep and extensive changes in the corium. The greatest degree of inflammation is exhibited about the hair follicles, which are frequently disintegrated by a serous and cellular exudate. Vesicles have their seat either in the epidermis or in the walls of the hair follicles. The persistence of desquamation and of the infectivity of the scales is to be accounted for by the depth of the pathological process in the skin.

Some Experiments of the Relation between Audition and the Circulation of the Blood in the Head.—Hamilton Stillson relates some of his personal experiences in hearing. His left ear had for a time a slight tinnitus with slight lowering of hearing-acuity. The tinnitus was caused by tubal œdema. The writer then speaks of palpating the tube by means of the tongue thrust into the post-nasal space. Fixing the attention on the tinnitus would increase its intensity, and brushing the hairs at the external orifice of the auditory meatus would cause a different tinnitus—caused by the contraction of the muscles in that vicinity. Pressure on the mastoid bone increased the tinnitus and raised its pitch. Pressing against the mastoid tip of the tinnitic ear caused it to hear objective sounds louder and in a slightly higher pitch. Lying down increased the tinnitus and lessened the hearing-distance. With head suspended, in the tinnitic ear the hearing-power seemed at first slightly diminished and then increased, but no rhythm in the objective sound could be noticed. Moving the head to and fro in its vertical axis caused a peculiar bell-like tinnitus in both ears, more noticeable in the tinnitic one.

Treatment of Lupus Vulgaris with X-Rays.—J. T. Knox reports this case of a girl aged twenty years. The disease involved the nose and upper lip, and had already caused perforation of the nasal septum. The rays were applied for from six to ten minutes each sitting, every other day, placing the affected parts from four to eight inches from the tube, according to the density of the rays. The total number of applications was seventy-four. Improvement was noticed soon after the beginning. The unaffected parts of the face and head were shielded by means of a mask. A cure was effected.

A New Test-Meal.—A. E. Austin says that the Ewald test-meal consists of two rolls and two glasses of water; the meal of Riegel consists of soup, beefsteak, and a roll. That used in the experiments described by the author consisted of 2 gm. of dried egg albumen, compressed into half-gram tablets. These are taken with two glasses of water and the stomach contents are withdrawn one hour after taking. Among the interesting points brought out was the unreliability of the presence of lactic acid as a diagnostic symptom. It is also quite evident that impaired motility is the most important condition in the so-called nervous dyspepsias, arising probably from the lack of innervation dependent upon shock or worry. It may be present with either impaired or superabundant secretion of hydrochloric acid. The former condition is probably the more distressing from the formation of organic acids and gases. It is of interest also that the increased flow of gastric juice is always accompanied by a relative increase in the amount of hydrochloric acid, or it may be that lack of motility and diminished hydrochloric acid are associated, and the small quantity withdrawn is due to inability to remove the total contents of the stomach. Egg albumen in the form of tablets seems to fulfil all the conditions that attach to a successful test-meal.

Spinal Caries with Abscess.—Ernest B. Young gives an analysis of seventy-eight cases. Incision of the abscess was done in the majority of cases. The prognosis of spinal caries with abscess, apart from the cases in which the abscess opens spontaneously, seems to be very slightly influenced by the treatment accorded the abscess, although undoubtedly affected by the proper fixation of the spine. Considering the series as a whole, the mortality was about

thirty-five per cent. at an average period of three years and nine months after the first symptom, the mortality being slightly greater among those in whom the disease commenced before the tenth year. In both children and adults the most common cause of death seemed to be a gradual deterioration of the whole system. The causes of death in a few cases in which it was possible to get a reliable report were: general tuberculosis, 4; amyloid, 1; tuberculous meningitis, 3; shock of operation, 2; sepsis and renal, 1; phthisis, 1.

The Agglutination of the Patient's Serum of the Bacteria Found in Cystitis and Pyelitis, with a Consideration of the Pleomorphism of the Bacteria Found in These Infections, Especially as Regards Chromogenic Properties of the Staphylococci.—Thomas R. Brown reports three cases, in two of which there was an absolutely positive reaction, and a suggestive reaction in the third. A careful bacteriological study of over eighty cases goes to show that the colon bacillus is the commonest cause of cystitis and pyelitis in women, while various staphylococci, the tubercle bacillus, and the bacillus proteus vulgaris are also quite frequently found. The pleomorphism of the colon bacillus is very marked. Results obtained with the staphylococci suggest that many of what we now consider separate species may have arisen originally from a common staphylococcus, and the variations in cultural peculiarities, in chromogenic tendencies, etc., may have been directly dependent upon the various factors, favorable or otherwise, which surrounded the special micro-organisms since that time.

Value of Potassium Bicarbonate in Colds and Influenza.—Stephen Harnsberger states that potassium bicarbonate, given early, will in nearly every instance abort a cold very effectually and almost at once. The remedy is well borne by both elderly and weak persons. When the tonsils are involved or when the catarrhal inflammation affects the other air passages or the alimentary canal, its use is very effective. Pneumonia is not so frequent in such cases, and when it does occur its course is milder and shorter. The writer wishes, however, particularly to call attention to the influence of this drug in influenza. He gives gr. xxx. in a cup of milk every four hours during the day, and no other diet for forty-eight hours. If milk is not well borne, then cold water is used. He also believes that the action of this drug is greatly assisted by a cathartic, such as calomel, podophyllum, etc. When heart failure is imminent, then rest in bed should be enjoined. The writer believes that there is no superior treatment for influenza.

Acute Internal Hydrocephalus, a Clinical and Pathological Study.—Charles W. Burr and D. J. McCarthy report the case of a man aged thirty-three years, who was suddenly seized with fever, bradycardia, constipation, rigidity of the muscles of the neck, headache, stupor, and delirium. For three weeks the intensity of the symptoms varied greatly, after which the patient improved very much physically, but showed many of the mental symptoms of paretic dementia. One week later both fever and meningeal symptoms returned, and after lasting about a week again intermitted for four days, only to return again and end in death. On post-mortem examination only a moderate internal hydrocephalus was shown, with proliferation of the ependyma and ependymal glia, perivascular round-cell infiltration in the subependymal tissues, and sclerotic and degenerative changes in the choroid plexus. To determine the cause of the lesions, if possible, the writers instituted a series of experiments on kittens by injecting into the ventricles of these animals sterilized urine, glycerin extract of the adrenals, tuberculin, hydrochloric and carbolic acids. They conclude from their results that the non-purulent inflammation of the ependyma produced by acid irritants differs only in degree from the reactive changes following the injection of toxins into the ventricles. Changes in the ependyma without changes in the subjacent tissue probably do not occur. The inflammatory condition experimentally produced, by whatever agent, did not cause any increase in the ventricular fluid, and the only evidence of an exudate from the ependyma was the amorphous material which probably was made up of degenerated cells. The microscopical sections in the toxin experiments resembled the sections from the case under discussion. The mental condition of the patient corresponds to that seen in other auto-intoxications. Both of these facts point to the hypothesis that the changes found were secondary to a toxic condition of the ventricular fluid. The exacerbations which Quincke compares in their sudden development and variability to angioneurotic œdema appear to them to be rather the manifestations of varying intensity of auto-intoxication, such as occurs in uræmia and syphilis. Finally, the hydrocephalus alone by its mere mechanical action, if sufficient fluid is present, can cause many symptoms.

A Case of General Gaseous Emphysema with Gas Cysts in the Brain Found after Death and due to Bacillus Mucosus Capsulatus, with a Consideration of the Gas-Producing Properties of Certain Members of this Group in the Cadavers of Animals.—This case is reported by W. T. Howard, Jr. The patient was a white woman aged forty years. On admission to the hospital she was comatose and never regained consciousness. The pulse was 108 to the minute, regular and rhythmical. There was Cheyne-Stokes respiration, the apnœa lasting twenty seconds. The extremities were cold and cyanotic; the skin was cool and moist. Examination of the chest and abdomen gave negative results. There was incontinence of urine, and none could be obtained on catheterization. The patient was in the habit of taking large quantities of morphine. She died eight hours after admission. The clinical diagnosis was morphine poisoning. The writer presents the following summary: In the case reported in this article there was septicæmia with special localization of the micro-organisms in the brain, with gas cysts of the brain and general gaseous emphysema due to bacillus mucosus capsulatus (aerogenes group). The bacillus isolated from the organs of this case, as well as other members of the aerogenic group of bacillus mucosus capsulatus, can cause general gaseous emphysema in the cadavers of rabbits, either with or without the intravenous injection of sugar before the animal is killed; the gas, however, being most abundant and rapidly found in the former case. It is not impossible that some of the published cases of gaseous emphysema in which a bacteriological examination was not made may have been due to members of the bacillus mucosus capsulatus group. The writer then notes that Dr. Welch has called his attention to the possibility that diabetes may have existed in this case. The possibility must be admitted, since no examination of the urine was possible. There is evidence that certain bacteria incapable of producing gas in tissues and organs of the body under other conditions may do so in diabetics on account of the presence of an abundance of sugar.

Two Cases of Necrotic Broncho-Pneumonia with Streptothrix.—Charles Norris and John H. Larkin call attention to the rarity and importance of such cases. The first case was that of a man aged forty-five years; the second was of a man aged twenty-three years. The writers give the following *résumé* of their discussion: The two cases of broncho-pneumonia in men forming the subject of this article were characterized by intense catarrhal and necrotic inflammation of the bronchi and by the presence of numerous streptothrix colonies in the bronchial lumina. Introduction of the bronchial material of Case I. into the trachea of three rabbits induced pulmonary abscesses and empyema of the pleura and pericardium in one of the animals. Introduction of the bronchial material of Case II. into the ear vein of a rabbit and into the trachea of a second rabbit induced likewise pulmonary abscesses and empyema. The empyemal pus of these rabbits contained filaments and rods morphologically identical with those composing the streptothrix colonies of the human cases. From Cases I. and II. a streptococcus was cultivated on the ordinary media, the streptothrix not being isolated in culture directly from the human organs. By inoculating the fresh and sterile kidneys removed from a normal rabbit with the empyemal pus of a rabbit injected into the ear veins with the bronchial material of Case II., the streptothrix from this case was finally isolated in pure culture, and its morphological and biological characters were studied in detail.

Puttee Paralysis (?) after Enteric Fever.—J. W. Springethorpe reports the case of a soldier who suffered from a condition frequently seen in that class after typhoid. Examination disclosed marked wasting of the tibial muscles of the left leg, with apparent wasting of the peroneal and extensor muscles also. The muscles reacted to the faradic current, but with a noticeable weakness. Those on the right leg showed no present difference or abnormality. There had been no implication of the calf muscles and there was no present tenderness on pressure over the nerve trunks in that region. Under faradism and massage the muscles rapidly regained their normal reactions, and their action at the time of writing has become practically perfect. The trouble was thus confined absolutely to the muscles and surfaces supplied by the peroneal nerve, the musculo-cutaneous branch of which supplies the peroneus longus and peroneus brevis, together with the dorsal surfaces of the foot and toes, while the anterior tibial branch supplies the tibialis anticus, the long and short extensors of the toes, and the long extensor of the big toe, as well as the dorsal surfaces of the inner toes. This implication of the peroneal nerve suggested injury, and when symmetrical, bilateral pressure as the probable cause. Such a cause is at once suggested in the puttees used so extensively and indiscriminately by the soldiers in the South African campaign. On being asked the patient stated that the last few rounds of the puttees were fastened rather more tightly than elsewhere directly over the head of the fibula, and thus pressed the peroneal nerve against the bone.

Uncomplicated Æstivo-Autumnal Fever in Europeans in the Gold Coast Colony, West Africa.—A. J. Chalmers says that this is the most common fever experienced by Europeans in the territory named. Predisposing causes are chills, constipation, mental worry, excesses of any description, disease of an organ lowering the vitality, poor food or indigestion, and insolation. Infection occurs through mosquitos, the especial variety being called by the author Anopheles Kumasii. The cansation is the parasite called "Heamonenas præcox." At first small and unpigmented, it grows and may be from one-fifth to one-third as large as the corpuscle, and becomes pigmented. Clinically the type of fever is quotidian; rarely it is tertian, but these typical fevers may be altered and become almost continuous by slight complications without malignant symptoms. The principal symptoms and signs are headache, pains in the back and legs, sense of weariness, thirst, and anorexia with nausea. There is tenderness over the liver and spleen, which are enlarged. Vomiting is frequent, and the bowels incline to constipation. The pulse rate sinks below normal on the fall of temperature. Without malignant symptoms the mortality rate is very low. Treatment may be summarized as follows: During the rise, antipyretics and, if necessary, cold applications and aperients; during the remission, quinine and some saline diaphoretic mixture. If the temperature is over 104° F., phenacetin with calomel and a hot lime drink; after the attack, tonics.

Have Maternal Impressions any Effect on the Fœtus in Utero?—By William Duncan. A woman, in the seventh week of pregnancy, was photographed with her husband. When the wife saw the photograph she exclaimed that her husband's "right hand looked deformed as if it had only a thumb and little finger." On frequent subsequent occasions she showed the photograph to friends, always pointing out the deformity to them. When the child was born —after a normal labor—the right hand was deformed, and the resemblance to the father's right hand, in comparing the two photographs, is sufficiently striking. Now comes a very remarkable occurrence. The nurse in charge of the baby white out walking one day showed the deformed limb to a neighbor who happened to be a few weeks pregnant. She was very shocked, but remarked, "What a lucky thing that both arms are not deformed." This woman was duly delivered of her first child at full term, and "both its hands and feet were deformed." The mother was of a very nervous temperament. She often expressed her opinion that it was the shock of seeing the hand of the first patient's child that caused her child to be born deformed. She would allow no one to see the child. She has since been removed to an asylum. Both of the children, apart from the deformity, are well developed and healthy. No previous cases of deformity can be ascertained as having occurred in either family.

Arrested Mental Development following Depressed Fracture of the Skull; Trephining; Improvement.—Alfred Clark reports the case of a mulatto child aged eleven years, whose development was normal till her fourth year, when she fell backward striking her head against the leg of a table. On recovery from the immediate effects of the injury she seemed all right except that she had a fit about once a week preceded by a spasm of the right arm and leg. The mental faculties became stationary and the gait shambling. She developed a genius for mischievous destruction, so that she had to be closely watched. Examination showed a depression in the left occipital bone near the parieto-occipital suture and about two fingers' breadth from the middle line. It was about an inch and a half long and three-quarters of an inch wide. Trephining showed the meninges enormously thickened and adherent. No fluid was obtainable by trocar and cannula passed into the brain. The adhesions were separated as far as possible, the disc of bone was replaced, and the wound closed. Recovery from operation was uninterrupted. The fits and spasms never returned and her mental condition vastly improved, so that three months later she seemed developing according to the standard of a child of four or five.

Myelopathic Albumosuria.—This affection is defined by T. R. Bradshaw as a disease characterized by an invasion of the cancellous tissue of the bones of the trunk by a cellular growth, by a disappearance of the osseous tissue, and by the presence in the urine of large quantities of a peculiar albuminous substance belonging to the class of bodies known as albumoses. The bones chiefly affected are the ribs, sternum, and the bodies of the vertebræ. Microscopically the structure resembles sarcoma. The condition is called "multiple myeloma." The disease occurs in the second half of life and seems more frequent in men than in women. The first symptom noticed is generally pain in the lumbar region. Later, the pains become more general. The urine contains a proteid which superficially resembles albumin but differs from it in several reactions. The writer gives the following characteristic reactions. (1) It coagulates at a comparatively low temperature (60° C. or 140° F.). (2) The coagulum is redissolved on boiling. (3) It is readily precipitated by hydrochloric acid, as well as by nitric acid, and the precipitates are dissolved on boiling. The diagnosis is easy, as the condition of the urine appears to be pathognomonic of the disease. The disease seems always fatal, but sometimes its course is remarkably prolonged. No treatment so far tried seems to have the slightest effect on the progress of the disease.

The Treatment of the Paroxysmal Stage of Whooping-Cough.—John Edward Godson describes the method which seems most satisfactory to him as follows: Commence at once with the continuous inhalation of creosote. Before the use of any anti-spasmodic remedies, the lungs should be cleared of bronchitis as much as possible. Belladonna seems effective in broncho-pneumonia. Moderate doses of antipyrin may be given in all cases, if or when the chest is fairly clear and the circulation good. Expectorants should be used at the same time. Wholesome food, fresh air, light and warm clothing are necessary. The writer gives the average length of time required for cure in a variety of cases last year as 19.8 days. These figures do not represent the benefit derived from the creosote treatment. The number of paroxysms is immediately much diminished in every case by the use of this drug.

The Propagation of the Filariæ of the Blood Exclusively by Means of the Puncture of Peculiar Mosquitos.—B. Grassi and G. Noè by proper experiments have demonstrated that when Anopheles bite, the larvæ of filaria immitis, which have been collected in the inferior labium, come out of their resting-place and are thus inoculated in the bitten animal, the mechanism of exit representing a most singular and admirable phenomenon for the diffusion of parasites. The experiments of these writers have been far more extended than their present report of them, but their entire results will be given at a later date. However, even now it can be stated that undoubtedly the blood filariæ, as the parasite of malaria, are inoculated by the puncture of special mosquitos, although in a different way. The exit of the larvæ does not, as Bancroft thought, take place through the œsophagus and pharynx.

Foreign Body Twenty-five Years in the External Auditory Meatus.—Arthur H. Benson reports the case of a man aged thirty-five years, who twenty-five years ago had put a

piece of slate pencil into his right ear, where it had since remained. He was very deaf and both ears were packed with cerumen. The ear was syringed and the cerumen softened with oil. The next day, when the ear was being syringed, a piece of slate pencil, three-quarters of an inch long, came out. It had a sharp point and had lain for twenty-five years jammed sideways in the meatus, causing no pain. After inflation by Politzer's method, the hearing in the right ear was improved to whisper at two metres and C. V. at seventy-five metres.

Ambidexterity.—James Sawyer is an enthusiastic advocate of ambidexterity. He states that an excellent way for the acquirement of this accomplishment is the learning of sinistral handwriting with pen and ink. When one can write comfortably with the left hand other accomplishments will become easy. Ambidexterity would prevent many occupation pareses. It would tend to a more equal use of the two sides of the brain, and might prevent or help some cases of hemicrania or perhaps some cases of hemiplegia.

Researches Concerning the Natural Immunity of the Dog against the Anthrax Bacillus.—In the discussion of this subject, M. Phisalix states that when a dog is inoculated subcutaneously in the thigh with a young culture of anthrax in which the spores have not yet developed, and when in the course of from five to eighteen days the animal is killed and the glands of the groin are examined, new cultures are obtained with characteristics completely different from those of the anthrax bacillus which has been inoculated. These new cultures are not virulent; but according to the length of time between the inoculation and the examination of the gland, and according to the intensity of the local reaction, the morphological characteristics of the microbe are recognizable or they are so changed that an observer not knowing the nature of the original inoculation would fail to recognize the micro-organism as that of anthrax. It is colored by the Gram method and does not form spores. The writer in his experiments has introduced virulent bouillon cultures contained in collodion capsules into the peritoneum of a dog. The transformation of the bacillus is due to the influence of soluble dialyzable substances. When the serum of a dog is used in the capsule as the culture medium the modification of the organism is far more rapid. It is probable that in the living animal the bactericidal and modifying power of the blood is due to substances which are elaborated principally in the glands and white blood corpuscles.—*Le Bulletin Médical*, September 26, 1900.

Fracture of the Skull; Hemorrhage from the Superior Longitudinal Sinus; Intervention; Cure.—G. Alexandre reports this case of a sailor aged forty-four years. He received a violent blow on the head, causing a severe hemorrhage which had resisted all efforts made to check it, till he was brought to the hospital six hours after the accident. The pulse was very weak and the face pallid. Blood was escaping by the mouth, nose, and from the wound. The wound was located in the left frontal region about an inch and a half above the eyebrow, extending laterally to the median line. Under chloroform anæsthesia the borders of the wound were excised, and a large resection of the frontal bone made so that the source of the hemorrhage could be reached. The flow of blood was stopped by a tampon. The recovery was uneventful. There was scarcely any deformity, only a small depression in the left frontal region. Hearing was slightly diminished on the left. There has been absolute amaurosis of the left eye since the accident. The results led to the conclusion that at the same time with fracture of the vault there had been section or compression of the optic nerve or of the chiasm by a lesion at the base.—*La Médecine Moderne*, September 26, 1900.

The Intervention of the Dentist in the Treatment of Syphilis.—Bruneau declares that in the course of syphilis, but principally during the first stage, the lesions of the buccal mucous membrane alone give evidence of the general infection of the organism. It is also true that it is to local causes of irritation, situated for the most part about the teeth, that the persistence of syphilitic ulcerations of the mouth can be attributed. Also the phenomenon of intolerance, mercurial salivation, which so often necessitates interruption of treatment, has no other origin than a pre-existing lesion of the gums. This is occasioned either by a poor state of dentition or by the presence of tartar about the neck of the teeth. Leaving aside external causes of irritation as tobacco, alcohol, etc., it is especially the teeth and gums that must be carefully examined in order to combat successfully the causes of syphilitic buccal lesions. The effort of the physician in treating syphilis should be: (1) To prevent the appearance of lesions of the buccal mucous membrane; (2) to anticipate and prevent the harmful effects of mercurial medication.—*La Presse Médicale*, September 26, 1900.

A New Method of Treating Tuberculosis by the Transfusion of Medicines by Means of Static Electricity, or the Method of F. Crôtte.—Ducamp speaks in terms of the highest praise of this method of treatment of the fearful scourge tuberculosis: Formic aldehyde is transfused through the affected organs by means of the currents of static electricity. The vapors of formic aldehyde are inhaled for a few minutes two or three times a day. The writer concludes from his own experience that tuberculosis is always curable in the first stage by this method, almost always in the second stage, and a third, at least, of the cases in the last stage. He thinks great credit should be given to H. F. Crôtte for elaborating this method.—*Gazette Hebdomadaire des Sciences Médicales*, September 23, 1900.

Bucco-Pharyngeal Tuberculosis.—Samuel Bernheim concludes that the etiology of bucco-pharyngeal tuberculosis, like that of every localized infection, is composed of three elements: the bacillus, the individual predisposition, and the port of entry. It may be primary or secondary, the latter being the rule. In this case the infection is carried by the lymphatics or the blood. When primary, it follows a direct inoculation. Among the causes which aid this infection are tobacco, poor teeth, and defective hygiene of the mouth. Its localization on the different organs of this region is very variable.—*La Tribune Médicale*, September 26, 1900.

Münchener medicinische Wochenschrift, October 23, 1900.

The Treatment of Obstipation.—E. Roos has endeavored to enrich our therapeutic resources by an attempt to stimulate a sluggish intestine to increased peristaltic activity by modifying its bacterial flora, adopting the somewhat unusual medicament of keratin-coated capsules containing pure cultures of the bacillus coli communis. These being obtained from the fæces of an individual having normal daily movements, it was supposed that on introduction into an intestine in which the reverse state of affairs existed a sufficient stimulus might be given to cause a more adequate peristalis. On experiment it was found that in cases of moderate constipation some improvement was effected, but that the cure was not permanent, which latter fact seems explicable to the author on the ground that the newcomers do not gain a permanent foothold in the alien mucosa and are therefore unable to continue their beneficial action indefinitely. Somewhat similar results were obtained with lactic-acid bacilli and yeast, the latter being equally effectual alive or dead.

The Atropine Treatment of Intestinal Obstruction.—Marcinowski contributes two cases to the list of reported instances in which an apparently imperative laparotomy has been avoided by the use of large doses of atropine. The first of these is that of a woman presenting the typical picture of intestinal obstruction, who six hours after the subcutaneous injection of gr. $\frac{1}{2}$ of atropine sulphate had a soft movement accompanied by flatus, and went on to make an uncomplicated recovery. The other case is that of a man who gave similar symptoms after apparently successful taxis for hernia. After fecal vomiting had set in, the same dose of the drug was injected with a like happy result. Absolutely no untoward effects were noted from the enormous amount of alkaloid given.

The Treatment of Gall Stones with Olive Oil.—Kurt Witthauer assumes a conservative position in regard to operative interference for cholelithiasis, and advises medical treatment in cases in which there is no daily febrile movement nor palpable gall bladder. The most successful agent in his experience is olive oil in large quantities (12–16 oz.), daily given by mouth as long as the patient can stand it, and then by rectum. The stools should always be sifted, that no stones may pass unnoticed. In one case a patient passed one hundred and thirty-seven stones while under this treatment.

The Effect of Johimbin.—A. Loewy says that this is the name given by Spiegel to an alkaloid extracted from the bark of an African tree called "yumbehoa" or "johimbehe," and appears to belong to the rubiaceæ. To another alkaloid the name of "johimbenin" has been given. A decoction of the bark of the tree is used by the African natives as an aphrodisiac. Loewy's experiments on mice, cats, and dogs were made with hydrochlorate of johimbin. The effects noted were a dilatation of the vessels supplying the genitalia, with swelling of the testicles and finally full erection of the penis. The local results were in fact very much like those of cantharides, but there seemed to be no irritant effect on the kidneys, and repeated trials on the same animal did not seem to produce any inflammatory changes in the parts affected. Overdosage caused, in warm-blooded animals, interrupted respiration, lessening of the pulse rate, and fall of blood pressure. If artificial respiration was continued, the pulse rate and blood pressure gradually diminished in a proportionate ratio until death occurred from cardiac paralysis. The action of the remedy appears to be confined to the genitalia exclusively in safe dosage. The author has given the remedy to one man, who took by mouth 5 mgm. of johimbin three times daily. The result was genital hyperæmia with powerful erections, though the drug did not seem directly to stimulate the libido sexualis.

Certain Cell-Problems and their Significance for the Scientific Foundation of Organo-Therapy.—D. Hausmann lays down the general proposition that there exists between the various kinds of cells an altruistic relation in the sense that one variety of cell exercises a definite influence over all other varieties, and that progressive changes in one variety cause in the others an altruistic hypertrophy, but retrogressive changes an altruistic atrophy. Organo-therapy builds itself upon this theory of altruism in cell relation and the specificity of cell function. Hence we may attempt to introduce into the body the particular substance of which it has been, by cell destruction, deprived. Naturally the substance introduced can replace only the positive result of the function of the lost cell, that is, the latter's internal secretion. In case of organs with a double function but little or no result can be expected. Hence organo-therapy is necessarily confined to organs with a single definite function. It is folly to introduce hepatic substance for liver troubles or kidney substance for kidney diseases. Also in pancreatic diabetes organo-therapy can have but a partial result, although this malady results from a failure of internal secretion.

Retrenchment of Lipomatous Abdominal Wall Combined with Operation for Radical Cure of Umbilical Hernia.—By J. B. Bullitt. The patient was a woman aged thirty-eight years, presenting a pendulous abdomen hanging down like an apron on the thighs, being on a level with the perineum when the patient was in a dorsal position and two inches lower when in an upright position. Careful examination led to the diagnosis of omental hernia. The contents of the sac could be partially reduced. Operation was done as follows: A transverse incision about six inches long was made two inches above the umbilicus, which had been previously stuffed with cotton and closed by means of three sutures. The hernial sac was encountered close to the skin, being covered by it and a thin layer of fat. The sac was found to contain a part of the transverse colon and omentum. The omentum alone was slightly adherent, but was not especially large and fat-containing, and, therefore, was not tied off. The intestine and omentum were easily returned through the ring. The edges of the ring could be readily brought in apposition, and closure was effected by mattress sutures taken from side to side through the base of the ring, closing it from above downward; a half-dozen heavy chromicized catgut sutures were necessary for this purpose. The sac was made up of the peritoneum on the inner side and the abdominal fascia on the outer, these two layers being amalgamated, inseparable, and forming one structure. The sac was then cut off about a half-inch from the margins of the ring, and a second running suture of No. 2 plain catgut was made, bringing the sac stumps together. The abdominal wall contained a layer of fat from three to four inches thick. The horizontal incision which had first been made was now prolonged in both directions to the two flanks, and a second transverse incision was made about seven inches below the first and joining the ends of the first incision in the two flanks. These two incisions extended through the fat down to the fascia; the enclosed portion of the abdominal wall, amounting to several pounds of skin and fat, was now dissected up and removed in the shape of a wedge. A continuous catgut suture was now applied from side to side, apposing the deeper portions of the exposed area. Above this, interrupted and buried catgut sutures were applied in tiers; and, finally, the skin was approximated by silk worm-gut sutures placed at intervals of several inches, and then a plain catgut suture applied in buttonhole fashion. Recovery was uneventful.

Report of a Case of Actinomycosis Hominis.—The patient of J. C. Oliver was a man aged forty-nine years. The method of inoculation could not be determined. The disease began as an ulcer on the inside of the right cheek just opposite to a clamp used for holding artificial teeth in place. The ulcer was curetted under cocaine and examination made for tubercle bacilli, but none was found. The use of the iodide was without benefit. The ulcer extended and became very painful, and the submaxillary gland of the same side enlarged, later softened, and was incised. The nature of the discharge led to a suspicion of actinomycosis, but microscopical examination at this time was negative. Other swellings appeared about the neck and under the ear. Discharge from the latter site presented the streptothrix of the disease and later the ray fungi. Previously, with a view of removing the focus of disease, the lower lip had been split midway between its centre and the right angle of the mouth, and the incision was carried backward in a curve to the lower part of the ear. Everything suspicious, including the submaxillary gland, was removed. Some black, sloughing tissue was found in the vicinity of the sinus in the submaxillary region. This was removed with a sharp spoon. The ulcer in the mouth was removed by carrying an incision completely around it. In the dissection of the neck, the lingual artery was divided. The patient finally died of a severe arterial hemorrhage from the submaxillary region, probably from the lingual artery, which had been divided at the time of operation. Because of inability to ligate this vessel, a hæmostatic forceps was left on the divided end of the artery for forty-eight hours. The artery was divided January 4, 1900; the fatal hemorrhage occurred March 3, 1900.

A Contribution to the Study of Intra-Abdominal Omental Torsion.—Weiner gives a summary of the histories previously reported by various authors and adds one from his own practice. From his summary it will be seen that omental torsion occurs more often in males than in females (presumably on account of the more frequent occurrence of inguinal hernia in men), that it is not met with in youth, and that it is found only in persons who have a hernia; although the diseased omentum is not always found in relation with the hernia. The portion of omentum affected may be small, or may be composed of almost the entire omentum. The etiology of the cases in which the omentum is not connected with a hernia is very obscure. In the other cases the etiology can generally be traced to forcible attempts at reduction of the hernia. In not a single case was the diagnosis made before operation. The cause for this is not far to seek. Not only are omental tumors extremely rare, but they have no characteristic symptoms; the symptoms they call forth are those produced by an abdominal tumor through its mechanical action. When the torsion takes place in connection with a hernia, the diagnosis is naturally made of an incarcerated hernia. In all of the cases the urgency of the symptoms was recognized, and a prompt operation was performed. There is a practical point of some value. If we cut down on a hernia that produced the symptoms of strangulation and find only a strand of omentum in the inguinal canal, we should always investigate the intra-abdominal portion of the omentum to make sure that there is no torsion present there.

Traumatic Rupture of the Small Intestine; Abdominal Section; Recovery.—By J. J. Buchanan. A boy aged eighteen years was hit in the abdomen with the handle of a pair of tongs with which he had been carrying a billet of iron. When seen five hours later there was no evidence of contusion, abdominal distention, or excessive rigidity of the abdominal muscles. Peristalsis was absent, and on this symptom, taken with the slight rigidity, moderate pain and two attacks of vomiting, an abdominal section was decided on. A rupture of the small intestine was found at the free border with eversion of the mucosa and escape of fecal matter. Peritonitis with exudation of seropus involved about one-third of the small gut. The wound was closed, and the head of the bed elevated ten inches as recommended by G. R. Fowler. With the exception of vomiting on the second day, the later history was without

incident. The author considers the points of interest in the case to be (1) the extensive peritonitis and free exudate present six hours of the injury, (2) the rupture of intestine without trace of external injury, and from what would appear to have been a slight blow; (3) the almost entire absence of symptoms apart from cessation of peristalsis and slight vomiting, and (4) the apparently favorable effect of Fowler's posture in the after-treatment.

A Study of One Thousand Operations for Acute Intestinal Obstruction and Gangrenous Hernia.—Concluding article by C. L. Gibson.

A Skiagraphic Study of the Normal Membral Epiphyses at the Thirteenth Year.—By E. R. Corson, M.D.

Zeitschrift für klinische Medicin, vol. xli., Nos. 1–4, 1900.

(Festschrift dedicated to Hermann Senator on the twenty-fifth anniversary of his professoriat.)

The Hydriatic Treatment of Some Common Dispensary Diseases.—The maladies discussed by H. Rosin are of such mild nature that they are never brought to the notice of those engaged in hospital work, and have received but little attention at the hands of text-book writers, but yet come often enough under the observation of the dispensary or practising physician, and frequently tax his resources to the utmost in their treatment. The first of these, variously called moysitis, myitis, or, preferably, as corresponding to neuralgia, the analogous condition in the nervous system, myalgia, may be etiologized under the two heads of cold and trauma. Of these the later is by far the most frequent and may take the form of awkward or misdirected movement overexertion in the regular performance of some normal act, such as the lumbago of gardeners and bricklayers, or, finally, may result from perfectly natural movements in those whose muscles have become weakened and incapable through wasting disease. Almost any region of the body may be affected, but the musculature of the trunk (neck, thorax, abdomen, lumbar region) is most frequently the seat of the trouble. The diagnosis is often difficult, for the subjective symptoms are wholly unreliable, and no dependence is to be placed on the statements of the patient, who usually locates his disease in heart, lungs, kidneys, etc. Tenderness limited to certain muscles with increased sensibility to faradism and hyperæsthesia of the skin help to differentiate the affection from rheumatism, neuralgia, bone and joint diseases, tabes, trichinosis, heart disease, stomach and liver disorders, etc., which must all be thought of and excluded. Internal medication is nearly always hopelessly ineffectual, while massage and electricity are too expensive for poor practice. Hydrotherapy affords the most suitable method of treatment, and may be applied as a Priessnitz pack, hot fomentations, or poultices of oatmeal or flaxseed, brine baths, sweat baths, or the half bath followed by cold effusions. An affection often simulating rheumatism or arthritis deformans is a combination of parasthesiæ, most often involving the hands or feet of women, and characterized by tingling, numbness, pain, stiffness, etc. In these cases burying the affected member in a pail of sand which has been heated in the oven, together with daily hot full baths prolonged for twenty minutes, is of great service. Various forms of disturbances of sensation connected with the stomach, independent of organic disease, the epigastric pulsation of neurotic women, and chlorosis, are all disorders likely to be greatly benefited by hydrotherapy in the form of hot packs, partial or full baths, cold douches, Turkish baths, etc.

Contributions to the Study of Diverticula and Dilatations of the Œsophagus.—Th. Rosenheim believes that these conditions are much more frequent than is usually supposed, and that with improved methods of technique the diagnosis will be made in many cases that would formerly have passed unrecognized. In his estimation the œsophagoscope is of the greatest value, though its use and the successful interpretation of the results obtained apparently require a degree of practice and experience to be expected only of the specialist. A manœuvre that is more easily applicable is the filling of a suspected diverticulum with a bismuth subnitrate mixture, and then employing the Roentgen rays, when the sacculation will be clearly outlined by the shadow of its metallic contents. Dilatations not secondary to new growths are usually due to atony of the œsophageal wall accompanied by more or less spasm of the cardia. The diagnosis is commonly easy, and may be made by the presence of regurgitation of undigested food which has not been acted on by the gastric secretions, dysphagia, and the œsophagoscope. In treating this condition systematic lavage is of the greatest value, both in relieving the subjective discomforts attendant on the condition and in correcting the tendency to inflammation nearly always produced by the presence of the decomposing food masses within the sack. The patient may safely be allowed to perform this operation himself, though the systematic overdistention of the cardiac orifice, which usually has also to be performed, should never be attempted by any but a physician. The application of astringent and antiseptic solutions to the atonic mucosa is often of benefit, as is also the regular use of electricity by means of the œsophageal electrode. Rest and general hygiene, which may have to be supplemented by the administration of sedatives, and plentiful nourishment (by the rectum if necessary) should be insisted on. Fat is an especially important article of diet, and may conveniently be given in the form of melted butter or olive oil a short time before meals.

Hanot's Cirrhosis.—Hasenclever ascribes to Senator the credit for having systematized the formerly conflicting views on the various types of cirrhosis, and by establishing definite pathological classifications having reconciled to each other the contradictory teachings of different writers. The essentials of his findings are as follows: (1) The size of the diseased liver will depend on the amount and the character of the adventitious connective tissue it contains. If no cicatrical contraction takes place, the organ remains enlarged and the function of vessels and parenchyma remains unimpaired, the case then representing a typical Hanot's cirrhosis. On the other hand, contraction of the tissue induces a diminution of size with concomitant destruction of liver cells; typical Laennec's cirrhosis. Portal hypertrophic cirrhosis and portal cirrhosis with jaundice due to gastro-duodenal catarrh are subclasses of this type. (2) If the formation of bile is diminished while its outflow through the biliary passages is unimpeded, no jaundice results. This is the case in Laennec's type, since the parenchyma cells are early destroyed, while the larger bile passages remain patent. In Hanot's form, however, opposite conditions prevail, since the bile is manufactured in normal amounts, while the ducts are narrowed through angiocholitis or periangiocholitis. (3) Ascites and venous dilatation of the abdominal wall and in the gastro-intestinal tract are due to congestion of the portal vein. (4) The swelling of the spleen has not yet been satisfactorily explained. Congestion alone is not a sufficient cause, and probably the same poisons (alcohol, syphilis, malaria) which affect the liver act on the spleen also.

The Relations between Diabetes Mellitus and Tabes Dorsalis.—W. Croner says that tabes and diabetes may occur simultaneously or consecutively in the same patient, or that either disease may simulate the other. In looking for a common cause syphilis is the most plausible, for while it is now universally believed that locomotor ataxia is not a syphilitic manifestation, specific infection undoubtedly precedes the nerve lesion in the majority of cases, and through a secondary arteriosclerosis, which is a well-known producer of diabetes, may also be assumed to stand in at least an indirect causal relationship to the latter disease. Granting the possibility of a common cause, the appearance of both diseases in the same patient is not so surprising, but it is also of interest to note that the diabetic condition may be only a secondary complication, possibly dependent upon the invasion by the tabetic process of regions of the central nervous system controlling the sugar metabolism of the body. Symptoms common to both diseases are general weakness and prostration, various forms of paralysis, ataxic gait, especially in the dark, parasthesias of the legs, patches of analgesia and anæsthesia, hypersensitiveness to cold, decreased sexual power, trophic and secretory disturbances, perforating ulcer, decubitus, hyperidrosis, muscular atrophy, absence of the patellar reflex, the occurrence of sugar in the urine, amblyopia and amaurosis, while the neuralgia of diabetes often closely simulates the lancinating pains of tabes. The pupillary reaction affords the most constant differential diagnostic sign.

A Case of Hypertrichosis Universalis with Precocious Sexual Development.—E. Lesser says that cases of excessive hairy growth must be carefully divided into two classes. In the first place there are instances of true hypertrichosis in which there is simply an abnormal growth of hair in those parts of the body where at least a suggestion of hairy growth is normally present. On the other hand, there are also cases in which every portion of the body, including the forehead and cheeks, is covered with a fine silky growth differing in nature from the ordinary hair. These are really lanugo growths representing instances of imperfect development, and the names "hypotrichosis" or pseudohypertrichosis lanuginosa have been proposed for them. An interesting feature is that defects in the dentition nearly always accompany anomalies of this class. The author describes an individual of the former type who at the same time gave evidence of premature sexual development. The patient, a girl aged six years, presented nothing abnormal at the time of birth, but in her second year a progressive enlargement of the breasts took place, which has continued until now they are of the size of a fist. In

the third year a menstrual discharge appeared which recurred eight or nine times and then stopped, while eighteen months ago a general diffuse growth of hair took place, which on the face is of the nature of a masculine full beard, and on the body covers the whole surface more or less densely except the hands and feet. The genitals resemble those of an adult in size and development.

Critical and Experimental Observations on the Relation between the Kidneys and Glycosuria.—Friedrich Richter's experiments tend to furnish a theoretical basis for the clinical observation frequently made that an intercurrent nephritis often lessens the intensity of cases of diabetes. French clinicians have made the observation that in individuals giving symptoms of contracted kidney three or four times the amount of sugar usually sufficing to produce an alimentary glycosuria had to be given before its presence could be detected in the urine. Acting on the theory that a damaged renal epithelium was less able to excrete sugar, the author gave animals such substances as aloin, cantharidin, or calcium oxalate, known to have a destructive effect on the kidney parenchyma, and then by administering phloridzin or diuretin was able to estimate the degree to which glucose elimination was influenced. In all cases the appearance of the sugar reaction was greatly delayed, and positive evidence afforded that the permeability of the kidney for this substance had been notably diminished. To what degree this, so to speak "mechanical," factor is concerned in the pseudo-cures of diabetes through nephritis, and whether some organic condition is not also to be considered, remain to be proven by further investigation.

The Pathology and Treatment of Typhoid Fever.—E. Barth lengthens somewhat the period of incubation of typhoid, which is usually given as two to three weeks, but which he thinks may extend even longer than four weeks, the conclusion being that at least five weeks' time are necessary for a thorough quarantine. Cases in which the disease develops in less than two weeks are likely to be severe, often ending fatally. In the matter of diagnosis the Widal and diazo reactions represent the greatest advances of recent years. Diarrhœa is not the typical symptom that the older clinicians made it; out of sixty cases only one-half the number exhibited it. Of the various intestinal antiseptics in use calomel is perhaps the most reliable, but its action depends rather on the thorough cleaning of the intestinal canal it entails than on any germicidal action, for at the outbreak of symptoms large numbers of bacilli have already gained access to the lymphatics and internal organs, where they are safe from antiseptic drugs. The Brand treatment properly applied is the most important factor in the treatment, but it requires careful adaptation to each individual case, and even then is not a specific but simply a general tonic and supporting measure.

A Contribution to the Etiology of Progressive Pernicious Anæmia.—W. Bussenius endeavors to elucidate somewhat the complex etiology of this disease by the description of a case in which the cause seemed less obscure than usual. The patient had been under medical observation for a period of eleven years, at the end of which time he was suffering from chlorosis and obesity. For over one and a half years his condition remained practically unchanged, the symptoms not being sufficiently serious to prevent the performance of his military duties. He was then given a furlough that a rest in the country might completely rehabilitate him, but instead of this his disease rapidly assumed a malignant form, and both the symptoms and blood examination pointed toward pernicious anæmia. In the absence of more satisfactory grounds the author attributes the destructive action on the red blood cells to the toxins contained in supposably inferior or even decomposed thyroid tablets surreptitiously taken by the patient to reduce his weight

OUR LONDON LETTER.

(From our Special Correspondent.)

THE HARVEIAN ORATION — GYNÆCOLOGISTS ON MEDICAL TREATMENT—GUY'S HOSPITAL—NEWSPAPER EDITORS ON HOSPITALS—STUDENTS AND A "DIVINE HEALER" QUACK—DRUNK OR DYING—PATHETIC DEATH OF A SURGEON.

LONDON, October 26, 1900.

PROF. CLIFFORD ALLBUTT delivered the Harveian oration at the Royal College of Physicians on the 18th inst. He discoursed on the forces opposed to Harvey and his researches, and showed the physiological darkness which preceded him. To put his great discovery in right perspective he thought we must have some vision of the history of philosophy, science, and medicine. Medicine, he said, had its sources among the Greeks, contrasting therein with theology and law; in the schools of Hippocrates and Alexandria it was based on natural history and anatomy. Galen, the first of physiologists and last of the great Greek physicians, practised the method of verification by experiment, introduced perhaps by Archimedes, subsequently lost till the time of Gilbert, Galileo, and Harvey. The orator then referred to some of the problems which engaged the thoughts and energies of men during the ages intervening, with special reference to philosophical questions which bore on medicine. He pointed out the weight of the social systems, opinions, prejudices, and habits against which Harvey had to contend. As an example, almost in the year of the publication of the "De Motu Cordis," the Paris parliament decreed that no teacher should promulgate anything contrary to the accepted doctrines of the ancients. Harvey's discovery burst like an earthquake on corrupt Galenism, venerable sophistries, current abstractions bequeathed by realism, and long-winded dialectics and dogmas based on uncritical subservience to texts. His work stood out even more against a background of superstition, magic, witch-burning, alchemy, etc. In terrestrial and celestial physics Galileo, persecuted as he was, had some strong current with him; Copernicus was before him, Kepler beside him; but in physiology upon the path of Galen the waters had closed as upon the track of a ship. Among Harvey's contemporaries none could claim a share with him in the discovery of the central fact of physiology, or in his application of the method which opened the way to his successors.

At the Gynæcological Society a paper by Dr. Heywood Smith gave rise to a discussion on treatment. Dr. Smith dwelt rather on the medical aspect of gynæcological cases, noticing briefly the several diseases in which other methods than operation might be considered. Mr. Skene Keith thought the society was apt to ignore the medical side of the specialty, and yet he thought the paper showed a hankering after operations, though in some cases surgery was put in the background.

Dr. Routh compared gynæcologists to politicians with their divisions of conservatives, moderates, and radicals. The circumstances and wishes of each patient must, he said, be considered. He related three remarkable cases illustrating the sympathy between the uterus and the mamma.

Mr. Bowerman Jessett commended the caution of the paper, and said that was the line of the prudent surgeon. He had not found treatment of any use in cysts of the breast, and if no improvement took place after a few months at the seaside he advised excision, as these cysts often degenerated into malignant disease. In inoperable cancer he had tried oöphorectomy and thyroid extract in five cases, but without benefit. Several years ago he had removed the ovaries of a patient and had just had to remove her breast for cancer, so the principle of the operation seemed at fault. If it were correct, a patient ought not to develop mammary cancer long after the ovaries had been removed.

Dr. Parsons said they knew little of the causes of endometritis, but one of them was prolapse, and this he treated by pessaries. For local applications he had tried carbolic acid, iodized phenol, and linimentum iodi for three years each, and found the last the most effectual. He observed some surgeons practised hysteropexy for displacements more than others. In his experience pessaries had usually sufficed.

Dr. Snow protested against treating tumors of the breast in patients over middle age. This was the time cysts occurred, and they degenerated into cancer sooner or later.

Dr. Jellett mentioned that the French school attribute one out of four cases of pyosalpinx to tubercle, a view confirmed by experience in the Rotunda Hospital of Dublin.

Dr. Macnaughton-Jones agreed with some previous speakers on the value of a discussion on these lines. He held that the advance of gynæcology was through pathological research, and on that alone treatment should be based. True conservative treatment did not consist in tampering with disease by uncertain methods, but in adopting radical measures when nothing could be expected from palliative ones.

Dr. F. Edge said each man did best along the lines he knew best. Some men might operate oftener than others, but all first used such general treatment as seemed possible and suitable. Personally he had not found oöphorectomy and thyroid administration of value.

Guy's Hospital seems to have been particularly unfortunate in reference to a class of fatalities in which charges of neglect or mistake have been made. The latest is a case said to be tuberculous meningitis sent to the hospital late at night by a local practitioner, and which was refused admission by the house surgeon on duty. It is not said whether any beds were available, but some of the newspapers have endeavored to get up a cry against the hospital by depicting a fancy scene in which boys were discharging the duties of the physicians and surgeons. It is a pity the writers of such paragraphs have not the honesty to inform themselves of the facts. Superficial inquiry would teach them that the house surgeons are by no means inexperienced boys, as they suppose, but the pick of the young men coming forward in the profession, invariably fully qualified and serving the hospital without fee or reward. It is a pity, too, that editors should insert sensational correspondence containing unsupported charges. One of these letters speaks of Guy's as "the slaughter-house," and declares that it is well known by that name. Another thinks mistakes prove the want of "outside control by representatives of the new London corporations," forgetting that these bodies are not supporters and that subscribers are. But that letter appears to be the production of one of the "anti" tribe.

I suppose you know all about Dowie, the faith-healing quack, as he hails from Chicago. He has come here to raise money for Zion City, which he will build, he says. Some medical students attended one of his lectures and shouted him down. On a second occasion others boo'd him as he approached the lecture room protected by a band of pugilists. Result—arrest and fine of some of the students. They would no doubt have been better employed in their studies than in disturbing the meeting of an arch-impostor who calls himself the "Divine Healer," but it seems a little hard to be severe on such an ebullition of disapprobation when unbridled violence was winked at during some of the recent elections.

Now and then cases occur showing the difficulty of diagnosis between "drunken condition" and "disease." A painful case came before the coroner on the 18th, in which a gentleman was actually seen to fall three times, but was taken off to the police station by the constable, who said he knew he had a broken skull. But a medical man was not sent for until the next morning!

Mr. A. S. Brown, F.R.C.S. Edin., died on the 17th after an accident. He was on his way to the South of France, and seeing a fellow-traveller fall off the quay at Boulogne waded in and rescued him, carried on artificial respiration for two hours, and then went on in his wet clothes to Paris, where he became so ill that he hurried home and died of pneumonia.

THE MODERN TREATMENT OF PULMONARY TUBERCULOSIS.

(A Criticism of a Paper on the Same Subject by M. J. Brooks, M.D., of Stamford, Conn., in the Medical Record, October 13, 1900.)

To the Editor of the Medical Record.

Sir: Without anticipating the annual report of the commanding officer of this institution, I desire to use certain facts, the result of observation both here and in previous experience, to controvert some of the very positive statements of Dr. Brooks. Constant association with consumptives and careful studies of the disease have not furnished me with the positive views on the subject that seem to be possessed by him. In view of the fact that many eminent students of phthisis and pulmonary tuberculosis are still divided on many points, particularly the biochemistry of the etiological factor and the histogenesis of tubercle, I do not regret my own somewhat agnostic attitude. I deem it my duty to use the facts in my possession to combat, if not invalidate, the misleading impression gained from reading Dr. Brooks' article. The citation of a large number of authorities, all on one side of a question, does not constitute argument, and that seems to be the distinguishing characteristic of this author's method of treating a vast subject.

In an easy, off-hand way he disposes of all the perplexing problems of this disease, and with an iconoclastic hand smashes the most cherished ideas of a large body of men, some of whom for a quarter of a century have studied and labored with pulmonary tuberculosis in all its phases, and have written volumes on the climatotherapy of the disease. The evidence accumulated by the workers in this field throughout the arid regions of the United States is at least worthy of citation, and must be taken into consideration, weighed, and studied before the efficiency of high dry climates in the treatment of pulmonary tuberculosis and phthisis is voted *nil*.

If I read Dr. Brooks' article understandingly, he believes, unequivocally, that both high and dry climates are unnecessary in considering the subject of phthisiotherapy. Notwithstanding the quotation of a number of authorities bearing him out in this, and that "the verdict of the International Congress at Moscow, 1897, was to the same effect," he has not brought any cold facts to bear in substantiation of his position.

It is true that there are no parts of the world suitable to human habitation that are free from tuberculosis. It is equally true that the natives of certain districts enjoy a partial immunity. According to Dr. Brooks, such comparative freedom from the disease is entirely due to the primitive and healthful mode of life of the people themselves. Now, is this invariably true? To my mind, for New Mexico at least, it is easy to prove the contrary.

It is claimed (and has been proved) that the inhabitants of eastern Colorado, western Texas, New Mexico, and Arizona enjoy a relative immunity to pulmonary tuberculosis. Excepting Colorado, the Mexican, now that the Indian has practically vanished, may be considered to constitute the bulk of native population in the districts named. It is a fact that he enjoys practical immunity from consumption. This freedom from the disease cannot be due to mode of life alone; for the Mexican is constitutionally filthy. Witness the smallpox which they have always with them. The Mexican is never so contented as when, with his family, he is close to a hot fire in a stuffy one-room adobe house, having but one window and one door, both of which are tightly closed even in summer time. The atmosphere of these places is simply intolerable to a white man, as I can testify from many personal experiences.

As a district physician among the poor of New York, I became accustomed to the dirty and unhealthful environment of the tenements, but have never seen anything approximating the unhygienic surroundings and life of the Mexicans. Their food is very objectionable from a health point of view, and is almost invariably fried in bacon-fat. Further comment on the habits of the Mexicans is unnecessary; and yet these people are practically immune to tuberculosis, and undoubtedly this freedom from the disease can be explained satisfactorily only by taking climatic conditions into consideration.

The vital statistics of Denver, Colorado, have an important bearing on the relation of pulmonary tuberculosis to climate. This is a modern city in every respect, and the habits and environment of the people in no way differ from those of other cities of equal size. The death rate of Denver, including the large number of consumptives who yearly make this city a Mecca, is no greater than that of New York (Manhattan), and, deducting the deaths from this alien tuberculosis, the death rate from tuberculosis is the lowest of any city of equal size in the world.

The report of this institution, which will be published early in the new year, promises to be instructive in this line of thought. Up to date the results obtained here confirm the therapeutic usefulness of the climate.

I do not believe that the most prejudiced advocate of climatotherapy thinks that there is anything actually specific in high and dry climates. It is simply that the climate of the region known as the arid plateau of the United States furnishes a particularly favorable environment for pulmonary invalids. It requires no argument to substantiate the opinion that dry climates are particularly healthful, and also that high altitudes are invigorating—even to people in good health. As a necessary corollary to dryness there is a maximum amount of sunshine permitting patients to remain comfortably out-of-doors three hundred and forty days out of the year. The characteristics of the climate of the arid zone of this country have been exhaustively described, and it is not necessary to take space to go farther into the subject here. The literature is voluminous and accessible.

Dryness and sunshine are inimical to all bacterial life, the bacillus tuberculosis having been proved particularly vulnerable to their action. To my mind this goes far to explain the relative freedom of the people of the arid zone from pulmonary tuberculosis, and the infrequency of reinfection among our patients.

A very important consideration in phthisiotherapy is the

protection of pulmonary invalids from intercurrent disease. Experience at this hospital bears directly and forcibly upon this point. Up to date two hundred and twenty-four patients have received treatment here, and their freedom from intercurrent disease, from colds to influenza, is proverbial and very striking. With the exception of an occasional cold, in no case has an intercurrent affection been observed, outside of those complications which the patients brought with them from the tropics, such as malaria, dysentery, etc.

The course of both pulmonary tuberculosis and phthisis is undoubtedly much modified by a residence here, and to attribute such modification to the climate seems the only rational thing to do. For instance, a goodly proportion of the two hundred and twenty-four patients mentioned above give a history of hæmoptysis before coming to New Mexico, but hemorrhages are strikingly uncommon here, and except in one or two instances in advanced cases a serious one has never occurred. Fully fifty per cent. of our cases are admitted febrile, but, as a rule, only a short rest is required to bring the temperature down to approximately normal. But fourteen or sixteen per cent. of the patients are permanently febrile, and these, with but few exceptions, were hopelessly advanced on admittance. Even in this class of cases the average daily maximum temperature is, I am sure, lower than that observed in the same class East, viz., 101° F. Night sweats are entirely confined to the febrile or mixed infection type, and even among them are rare and very amenable to treatment. Except in patients presenting a history of dysentery, diarrhœas are infrequent, and the so-called diarrhœa of phthisis is practically unknown.

It strikes me that no further argument is necessary to prove that high, dry climates present ideal conditions for the application of the fresh-air-diet treatment which here, of course, as elsewhere, forms the basis of therapeutic measures. Dr. Brooks, or any man who fails to take the "demonstrated truths" of this subject into consideration, must at least expect to have his motives questioned. For the guidance of the profession of the United States the dictum "send your consumptive patients west as soon as the diagnosis is made" still remains unimpeachable. A ruthless application of this rule, regardless of the patient's financial condition, is necessarily absurd, and for the many to whom a sojourn in the West or like region is impracticable, I, for one, certainly anticipate great results from the fresh-air-diet treatment, even in damp, unstable climates such as that of Boston or Edinburgh; in fact, such results have already been obtained. Nevertheless, the statistics compiled by workers "out West" proved beyond a doubt that better results will always be obtained in climates which present the features emphasized in this paper. The question of the applicability and usefulness of our Western climate in phthisiotherapy would be settled for evermore were it but possible to get the testimony of the thousands in whom the disease has been arrested or cured in this climate, and who constitute so largely the white population of the "arid zone."

With a characteristic touch Dr. Brooks negatives the whole of serum therapy in pulmonary tuberculosis. Some very eminent men still withhold a positive opinion on this subject, and others sincerely believe in the limited usefulness of some of the sera already on the market. Most medical men, I am sure, anticipate a "cure" along biochemical lines, and in a field already so prolific of results it does not pay to be scornful. Dr. Brooks is undoubtedly right in discouraging the use of sera in advanced or mixed-infection cases, as a serum derived from tubercle bacilli is manifestly useless in such cases. The point is, however, that the most enthusiastic advocate of sera does not advise their employment in cases exemplifying this type of the disease. Even the old tuberculin has a fixed, if somewhat uncertain, value in the treatment of lupus, and I myself can testify that, as a sequence of the use of this agent for diagnostic purposes, I have witnessed, in a number of instances, a sudden and striking impetus to recuperative power that is difficult to understand on any other basis than specific action. In the fact of the evidence against this agent in phthisiotherapy it would be absurd to advocate its use. However, the fact remains that the seemingly antagonistic action of tuberculin must be explained before serum therapy in pulmonary tuberculosis is filed with the "back numbers."

While so generally nihilistic toward most special therapeutic measures, Dr. Brooks exhibits a marked bias in favor of inhalation of antiseptic vapors, and quotes Peurose, of Johns Hopkins, to the effect "that the antiseptic action of inhalation is manifested by the rapid disappearance of pus organisms from the sputum." In the examination of thousands of specimens of sputum, and careful comparison of cases, I yet fail to understand the significance of adventitious organisms in the sputum. One point is clear to me: in the majority of cases in which bacilli tuberculosis are found in the sputum other organisms are absent, or few in number; *per contra*, as soon as the bacillus tuberculosis disappears from the sputum the adventitious organisms, including pus organisms appear in enormous numbers. In fact, in our work here the appearance of adventitious organisms is heralded as rather a favorable prognostic sign. Now, wherein lies the significance of the occurrence of these organisms in the sputum, and what is the use of removing them if present?

A number of years ago the futility of medicating the atmosphere of institutions was proven, and I believe it perfectly safe to say that the constant inhalation of pure air is the only inhalation of confirmed value.

I do not say that medicated inhalations are useless, but simply of very limited applicability in certain bronchial cases, and, if I have understandingly studied the literature of the subject, this opinion is now classic.

EARL SPRAGUE BULLOCK, *Surgeon U. S. Army.*

CORNING'S SUBARACHNOID COCAINE ANÆSTHESIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I beg to call attention to a letter by Dr. William J. Robinson, which appeared in the MEDICAL RECORD of November 10, 1900. After an introductory panegyric on my work in neurology the author of this interesting epistle has this to say:

"It is the method of subarachnoid anæsthesia that promises to work a revolution in general surgery and obstetrics, and the credit of the method undoubtedly belongs to two men—to Prof. August Bier and to Professor Tuffier, to the first as the discoverer of the method, and to the second as its popularizer."

Had the author looked into the subject more carefully, he would have found that in my book on "Pain" (J. B. Lippincott Company, Philadelphia, 1894) I have, under the head of "Irrigation of the Cauda Equina with Medicinal Fluids" (pp. 247–254), devoted six pages to the consideration of subarachnoid anæsthesia, which I devised and executed in 1888, and published five years before either Bier or Tuffier entered the field. Bier's paper was published in 1899[1] and Tuffier's in 1899 and 1900.[2]

Again, your correspondent observes, "He [Corning] was certainly one of the first to perceive the possibilities of the method of spinal cocainization." This is highly diverting in view of the fact that not only was I the first to perceive its possibilities, but also the very first actually to anæsthetize the cord—all this in 1885, before such a thing was even dreamt of! Whatever the crudities of my provisional hypotheses, they led me to the establishment of the action of cocaine on the cord; and, as has been pointed out over and over again by others, to the full development of subarachnoid cocaine anæsthesia, years before Bier or Tuffier or any one else entered the field.

Your correspondent intimates that I was "uncertain whether the method would ever find an application in genito-urinary or other branches of surgery." This is not true; I said in my first paper, published in 1885: "Whether the method will ever find an application as a substitute for etherization in genito-urinary or other branches of surgery, further experience alone can show!" This was certainly a correct attitude fifteen years ago; for even at this late day, and despite the many trials made of it, the method as a permanent adjunct to surgery is still *sub judice*.

As a neurologist this was sufficient, and more; but, I may add, as a matter of collateral interest, that I even tried to enlist the co-operation of a prominent surgeon in the matter, but without success. Nor ought we to judge him harshly for this; for at that time penetration of the meninges of the cord seemed as venturesome an undertaking as did mutilation of the peritoneum at a more remote epoch.

Your correspondent states that subarachnoid anæsthesia "promises to work a revolution in general surgery." This, of course, is absurd.

It is not scientific to make a fetish of the cerebro-spinal fluid, whose appearance is by no means an infallible herald of the success of the injection. Inversely, this fluid may, for some reason or other, fail to appear in the needle; and yet, if the preliminary measurements which I recommend for the purpose of insuring the penetration of the membranes be taken, the injection may be a success.

I think I can trust the profession of this country to deal with those who pervert, ignore, or skate blithely over much that I have written; and neither petty casuistry nor mincing cavil can debase the import of recorded and conceded fact.

J. LEONARD CORNING.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 1, 1900.

WILLIAM H. THOMSON, M.D., PRESIDENT.

The Etiology of Cystitis.—DR. WILLIAM K. OTIS read this paper. He said that it was only comparatively recently that it had been generally recognized that the one constant and determining factor in cystitis was some microbic infection. For our knowledge on this subject we were indebted to the researches of Pasteur primarily. At first, it had been supposed that this infection was always the result of the introduction of the micrococcus ureæ, but further research had isolated no less than twenty micro-organisms in the urine of cases of cystitis. The micro-organism that occurred most frequently and of late attracted the most attention was the bacterium coli commune. Because of its varied morphology it had been known by a great many different names. The most important micro-organisms in connection with the study of cystitis were the bacterium coli commune, the staphylococcus aureus, albus, and citreus, the gonococcus, and the tubercle bacillus. Next in frequency to infection through the urethra came infection through the blood as a cause of cystitis. Inflammation of any organ might give rise to a metastasis to the urinary tract, but, as a rule, the microbes were derived from the alimentary tract. This might be the case even without any symptoms pointing to disorder of the bowel. It was not improbable that at times microbes from the intestine circulated in the blood of every one. The kidney was one of the organs in which the blood most frequently deposited microbes. Another mode of infection was by the breaking through of an adjacent abscess. In the condition known as bacteruria the bacterium coli commune was present in enormous numbers for a long time without giving rise to any inflammation. Such a phenomenon was certainly extremely puzzling. The gonococcus and the tubercle bacillus could not be regarded ordinarily as a direct cause of cystitis. In so-called gonorrhœal cystitis the urine taken directly from the bladder without any chance of contamination from the urethra contained very few gonococci. It was generally conceded that tuberculosis of the bladder was always secondary to tuberculosis of the kidney or of the lower uro-genital tract. Infection took place most frequently from the kidney. The resistance of the mucous membrane of the bladder to the tubercle bacillus was very great, the urine sometimes containing tubercle bacilli for years without the bladder becoming infected. In some cases the bladder became involved by rupture into it of a tuberculous prostatic abscess. A previous simple cystitis not infrequently prepared the soil for tuberculous infection. In 1888 Guyon had demonstrated that pure cultures of various micro-organisms might be introduced into the healthy bladder without producing cystitis. It was evident, therefore, that there must be certain predisposing factors. When the resisting-power of the mucous membrane of the bladder was reduced by the presence of a foreign body or of residual urine, micro-organisms rapidly produced inflammation. The presence of residual urine alone without the coexistence of micro-organisms did not give rise to cystitis; hence the great importance of maintaining asepsis when there was residual urine.

Sterilization of Instruments.—Metal instruments could be readily sterilized by boiling for ten minutes in a solution of carbonate of sodium. Silk or gum catheters could not be boiled, hence they must be so constructed as to make mechanical cleansing easy and efficient. It was most important to have no blind end. The mechanical cleaning was best accomplished by the use of warm soapsuds immediately after the use of the instrument, the soapsuds being driven through with a syringe. They should be wiped and exposed to a dry heat of 100° F. for ten minutes. It was essential that they should be dry on the outside, and that the different instruments should not come in contact during this drying process. Sterilization by formaldehyde or paraform was satisfactory, but the instrument should be washed with sterile water before being used again, otherwise when introduced it would cause smarting. Great care should be taken in instructing those who were about to begin self-catheterism as to the precautions they must take to keep the bladder aseptic. The patient should have a medium-sized coudé catheter, and twice as many of these as are needed each day. The urethra should be irrigated before catheterization. A good lubricant for urethral instruments should be aseptic, and easily miscible with water. Vaseline or fat should never be used as a lubricant for catheters, as it adhered to the wall of the bladder and prevented the escape of such micro-organisms as chanced to be in the urethra. The bladder should be filled after instrumentation with formalin solution 1 : 1,000, nitrate of silver in two-per-cent. solution, or potassium-permanganate solution 1 : 1,000. After having been retained in the bladder for three or four minutes it might be permitted to escape. The best internal antiseptic for the bladder was urotropin in doses of gr. viiss.

The Seed and the Soil.—DR. E. L. KEYES said that he could testify to the fact that the bacterium coli commune often existed in the urine in large numbers, and for years, without giving rise to cystitis. A case was cited in which for upward of twenty-five years bacteruria had been present, and had eventually passed away, although during all this time the man had been catheterizing himself and very carelessly at that. In this connection one should not lose sight of the relation between the seed and the soil. When the bladder was atonied, when the circulation was poor, as it usually was in cases of enlarged prostate, when the person had indulged too freely in sexual intercourse, or had refrained therefrom through a long period of sexual excitement, the soil was likely to be rendered favorable for microbic infection. Perhaps the prettiest demonstration of the importance of the soil was the famous experiment of injecting into the ear of a rabbit a micro-organism known to be capable of causing cystitis. The animal being healthy and well, no harm came from this inoculation. Another rabbit was then given a similar injection after one kidney had been bruised by squeezing the loin. The animal developed an abscess of the kidney on that side, but no lesion of the other kidney. Regarding sterilization it seemed to him that all metallic instruments were best sterilized by passing them through the flame of a Bunsen burner, and rubber instruments were best sterilized by boiling. He preferred washing out the bladder with a 1 : 1,000 solution of nitrate of silver after the introduction of instruments. He never used either bichloride or formalin because he had found them irritating, and he would be afraid to use a two-per-cent. solution of nitrate of silver indiscriminately.

Individual Tolerance.—DR. L. BOLTON BANGS said that the vulnerability of the individual varied at different times. He had known one man to carry his catheter in his hat and lubricate it with saliva, and yet he had succeeded in avoiding any serious complications. Another man by careless catheterization had started an attack of cystitis necessitating the use of the self-retaining catheter. While on the commode, this catheter had slipped into the bowl, but the man

had fished it out from the mass of fæces and without any hesitation had slipped it back into the bladder. There had been no alarming consequences of this extraordinary act. The directions for insuring cleanliness should be as simple as possible, and every effort should be made to keep the general health at the highest point.

Dr. Eugene Fuller cited a recent case in proof of the improvement that would take place in a cystitis from relieving the condition of atony and improving the general health. He said that the gonococcus might be present for some time and do no harm in the bladder unless a mixed infection should occur.

Bladder Washing a Great Safeguard.—Dr. A. B. Johnson recommended for self-catheterization particularly the use of a special form of rubber catheter, of the coudé pattern, having a solid end. Because of this feature it was easy to pass the instrument in cases of marked prostatic enlargement. The patient should be directed to boil the instrument for a few minutes before use, and to wash the hands and glans penis before introducing the catheter. It did not seem to him of great importance what antiseptic solution was used for washing out the bladder after instrumentation, but it was of the first importance that this washing be done.

Dr. Ferd. C. Valentine spoke of the utter innocuousness of the gonococcus when thrown into the healthy bladder by intra-vesical irrigations. He had adopted the plan of filling the urethra with a glycerin emulsion of iodoform before introducing an instrument, for the reason that slight injuries were inflicted upon the urethra, and in this way these abrasions were at once cleansed and made aseptic. Several cases had been reported recently in which stones had formed in the bladder around hairs which had been carried in on catheters.

Dr. B. Lapowski said that Wassermann had discovered the gonococcus pure in the tissues of the bladder. Three other investigators had detected the gonococcus in urine drawn from the bladder aseptically. The fact that so many cases of gonorrhœa did not have cystitis was no argument that it could not occur.

Dr. A. Jacobi spoke of soil and vulnerability. He said that, as a rule, micro-organisms would not gain entrance through sound and healthy epithelium, or when the circulation was sufficiently active. Tuberculosis of bone was almost invariably found at first in the ends of the bones, and where the epiphysis was growing—in other words, where there were congestion and slow circulation. It was because of these that the tubercle bacilli gained a foothold. As long as the bladder was fairly healthy he did not believe cystitis would arise simply from the presence of the bacterium coli, unless these bacteria were virulent as a result of certain special changes going on in the intestine. The bacteria found their way into the bladder either directly or through the blood. When there was very little uric acid and much urea, decomposition was readily set up.

Dr. Otis, in closing, said that he had not intended to say that he used a two-per-cent. solution of nitrate of silver, although this was employed by some. He personally favored a strength of 1:1,000. For the first few days of catheter life it was well to give urotropin internally, and insist upon the patient remaining in bed. So-called gonorrhœal cystitis was almost always the result of other organisms than the gonococcus.

Inebriety.—No single remedy is capable of meeting a wider range of conditions than the Turkish hot-air baths, with free massage.—Dr. T. D. Crothers, *Virginia Medical Semi-Monthly*, October 12th.

Clinical Department.

PERFECT RECOVERY FOLLOWING GANGRENE OF THE SCROTUM AND PENIS.[1]

By EVERARD HAMILTON RICHARDSON, M.D.,

ATLANTA, GA.

Because of its being unique—certainly cases of this character do not very frequently come under the observation of the physician and surgeon of the widest experience and having the largest clientele—this case of exceeding interest to myself (and I indulge the hope that it may prove not less so to this august body of practitioners) is reported.

E. H. T——, occupation bank cashier, native of Georgia, now a resident of Sanford, Fla., personal and family history excellent, was treated there by several physicians. He came to me direct from the Plant System Railroad Hospital located at Sanford, Fla. Summoned by wire on June 8, 1900, I met this patient at the Union Depot at Atlanta, Ga., and found him in a Pullman sleeper almost in a state of collapse, with a pulse of 120 beats per minute, temperature 103° F., and bathed in a profuse perspiration from exhaustion.

I immediately administered gr. $\frac{1}{30}$ of strychnine hypodermically, gave him a drink of brandy, and placed him in the Grady Hospital Ambulance, sending him to St. Joseph Infirmary. There from the patient himself and his friends the following clinical history of the case from its inception was obtained. Upon May 16, 1900, the patient observed a small pimple upon the integument a short distance above the os pubis which was slightly red; shortly afterward the surrounding tissues became swollen and somewhat tender to the touch. In twelve hours from the date of the appearance of this apparently insignificant pimple, the inflammation extended to the penis, where in addition to the general swelling and redness then obtaining, there was intense itching with burning in the affected parts. The pain at no time was severe, but the burning and itching were great. At this juncture, forty-eight hours from the appearance of the initial lesion, the penis turned black and simultaneously the scrotum became involved, and a few hours later also turned dark. The physicians in attendance denominated the malady gangrene. The patient was now placed under an anæsthetic, and the necrotic structures were removed by the surgeons in charge of the hospital.

An examination of this patient, after coming into my charge, revealed the fact that the integument of the penis had been entirely destroyed, the destructive process extending down to the corpora cavernosa and the corpus spongiosum. The crura and suspensory ligaments of the root of the penis were intact, and the glans penis had escaped, as the line of invasion did not extend beyond the corona glandis. Three-fourths of the scrotum had been entirely destroyed by the gangrenous process down to the tunica vaginalis. The spermatic cords, the testes with the epididymis were in good condition, but the testes were entirely bare of covering and were supported only by the spermatic cords.

The penis and testes were thoroughly cleansed with a solution of mercuric chloride 1:3,000, enveloped in ten-per-cent. iodoform gauze; rubber tissue, absorbent cotton, and a double spica bandage were applied. Constitutionally he was supported by the regular administration of sweet milk, beef juice, raw eggs, and peptonoids. He was also placed upon tincture of chloride of iron, and strychnine with tonic doses of quinine were continued. Antiseptic dressings with

[1] Read before the Mississippi Valley Medical Association at Asheville, N. C., October 9, 1900.

the addition of solution of hydrogen peroxide in full strength and a twenty-five-per-cent. solution of balsam of Peru in olive oil were continued daily. There was very grave impairment of the patient's nutrition, emaciation was extreme, and the patient was but little more than skin and bones. His general condition was such at this time as to preclude the propriety of considering any operative procedure. From day to day it was difficult to discern any improvement, but under the régime instituted the patient's appetite and strength slowly improved. The gangrenous process ceased its havoc, and the line of demarcation was clearly established. But not until the lapse of twenty-six days from the time he came under my observation, did I believe it safe to risk the shock of operative interference. For good reasons he was removed from St. Joseph Infirmary to a private house.

At my instance, on July 2, 1900, Dr. W. F. Westmoreland was called in to see this case with me. It did not seem possible that there was left a sufficient amount of the scrotum for an adequate covering for the left testicle. We decided, however, to make the attempt to save both testicles. I regret that owing to a hurried call from the city Dr. Westmoreland did not again see the case after his first visit until the completion of the operation, when the patient presented himself at his office only to show a perfect specimen of restored manhood.

On July 4th, assisted by my son, medical student Everard Dugas Richardson, and by Dr. Pierce M. Butler who administered the anæsthetic, I dissected off the scrotum as high up as possible, using strict antiseptic precautions, and succeeded by pushing up the testes and introducing silkworm-gut sutures and pulling down the scrotum in entirely covering both testes with integument. A small piece of gauze for drainage was left in the centre of the wound, and with the exception of this point perfect union by first intention was secured.

The patient was slow in regaining his wonted strength, but by September 1st his recovery was complete, and on October 1st he was a splendid specimen of physical manhood, strong and robust.

Before giving my conclusions concerning this case, I wish to state that from my own long and intimate knowledge of the family history, morals, and habits of this patient, I am able absolutely to exclude the suspicion of any venereal taint as a causative factor in the production of the lesion. The patient's perfect recovery and his present superb health warrant the elimination of arteriosclerosis, atheroma, chronic nephritis, and diabetes mellitus as etiological factors in the production of the case of gangrene under consideration. The history of the case does not justify the assumption that the gangrene was due to any obstruction of the circulation or to the intensity of the inflammation, because at no time did the inflammatory process run high. We are also able to exclude embolism and thrombosis.

It is well known that there are various causes of gangrene, and that there are various micro-organisms that may be concerned in its production, and it is true that no specific germ producing gangrene has yet been discovered, though I believe its discovery will be made by bacteriologists in the future.

Reviewing the history of this case from its inception, and instituting a careful analysis of the symptoms seriatim as they occurred, I conclude that: The initial cause in this case was an abrasion of the skin at the spot where the small pimple first appeared. This was the portal of entrance of the pathogenic bacillus, the streptococcus erysipelatis, from which infection occurred. Later there occurred a second infection by the cocci of gangrene, rather than that this was a terminal phenomenon of erysipelas.

Fehleisen teaches us that the streptococcus erysipelatis presents distinct differences from the streptococcus pyogenes, and that we never have suppuration in erysipelas except from a mixed infection.

Dr. William H. Welch has recently contributed a most admirable article to the transactions of the Massachusetts Medical Society, showing a collection of forty-six cases of emphysematous gangrene, in all of which Bacillus aerogenes capsulatus was demonstrated to have been present. To me it is a matter of profound regret that no bacteriological examinations were made in the case under consideration. I also lament that I did not have photographs taken in order to demonstrate the local destruction of this patient's genito-urinary apparatus, as well as to portray the perfect recovery after the performance of the simple operation which I have narrated.

A CASE OF CARBOLIC-ACID POISONING, WITH A QUESTION CONCERNING ASPHYXIA.

By H. E. KENDALL, M.D.,
SIDNEY, NOVA SCOTIA.

The patient was a child under two years of age. Pure carbolic acid of unknown quantity had been taken about twenty minutes prior to my arrival. The mouth and throat were white, the face was livid, the pupils were dilated and fixed, and the breathing was stertorous. The child was completely unconscious. This unconsciousness, the mother told me, had come on a very few minutes after the acid was swallowed.

I put a rubber catheter into the stomach and forced in a pint and a half of a solution of magnesium sulphate and brandy. This I attempted to siphon out, but unsuccessfully as the child had just previously eaten a substantial meal. All attempts to produce emesis failed. The child was rapidly getting worse. The pulse was scarcely perceptible, and the respirations were beginning to slow down, when it occurred to me to draw forward the tongue, as I observed considerable sinking of the supraclavicular regions with inspiration. On doing so air entered the chest more freely, the face assumed a better color, and in ten or fifteen minutes the pulse had become decidedly better. Then the child began to cry, and from that on recovery seemed to take place. For a time the breathing would again become bad whenever the tongue was let go; in short, it was exactly like a case of poisoning with chloroform in anæsthesia. The child knew its mother in about two hours. After this the breathing became somewhat croupy, and I prepared to intubate with an O'Dwyer tube, but this did not prove to be necessary. Vomiting occurred when consciousness was returning, and I then saw that but little carbolic acid had got as far as the stomach—at least so I judged from the absence of its odor in the material vomited. The next day I found the child with a burnt mouth, but otherwise pretty well.

From this case I will not generalize, but there are some pretty important facts which I will note:

(1) The child after swallowing carbolic acid was apparently dying very rapidly with symptoms that might reasonably be thought to be produced by the systemic effects of the poison.

(2) These symptoms were not the result of systemic influences; otherwise they would not have disappeared so quickly.

(3) The unconsciousness, dilated pupils, lividity, and heart failure were the result of asphyxia, and asphyxia was the result of the local action of the poison upon the structures about the tongue and epiglottis.

CHYLOUS ASCITES.

By J. W. KALES, M.D.,

FRANKLINVILLE, N. Y.

A MAN, thirty-four years of age, died in this village August 19, 1900. During the latter part of December, 1899, he noticed some swelling of the left scrotum and adjoining parts. This swelling invaded the left lower extremity, and gradually extended into the abdominal cavity, and then extended to the right lower extremity. Many able physicians were consulted. The disease continued uninfluenced by treatment until relief came by death. Several diagnoses were made. About a month before death, the enlarging abdomen interfered with respiration, and tapping was employed to secure temporary relief. On the first occasion about one gallon of fluid was removed. This fluid appeared like rich Jersey milk. When allowed to stand, a thin layer resembling cream collected at the surface. The fluid accumulated quite rapidly, and was removed every four or five days. The writer removed about three quarts the day before death. This was a case of chylous ascites. The most curious part of the case is that no one even suggested chylous ascites until the fluid flowed through the trocar. No autopsy was held, because the writer was suffering from a fractured elbow.

No adequate cause has been assigned. The patient was born and reared near this place. He has lived near here all his life, except a year in Tennessee and a year (1897 and 1898) in the Klondyke. He was somewhat intemperate in the use of alcoholic liquors. It is regretted that an autopsy could not be held, as it would probably have revealed the connection between the lymphatics and the abdominal cavity.

UNIVERSAL ANKYLOSIS.

By H. A. ELLIOTT, M.D.,

BARNET, VT.

DURING my summer vacation my attention was called to a peculiar case in an adjoining town, and for the purpose of investigating it I drove over to see it, thinking its report might be of some interest. It is an extreme case of rheumatoid arthritis, and as I have never seen or heard of such a case before, I should like to have it published.

B. A——, aged forty-four years; white, married, residing in New Hampshire. Parents are both living. The mother is sixty-eight years old, and has slight rheumatic tendencies, but no disablement. The father is seventy years old, and has no rheumatism.

Previous to 1887 the patient had attacks of rheumatism which disabled him partially from the time he was twenty-one years old, and thirteen years ago he was obliged to take to his bed, and ankylosis set in very soon in almost every joint in the body, the process being accompanied by great pain.

I saw the patient in August, 1900, after the thirteen years of helplessness. The right arm and hand were across the chest, the left was on the abdomen, the legs were semiflexed at knees, the hips were partially flexed at the pelvis; the cervical vertebræ were all in their anatomical position, and the jaw was set. All of the above joints were immovable except for a very slight motion of the right hip and of some of the phalanges. There was not enough motion to enable the patient to help himself in the least.

Some of his teeth were removed to permit of the introduction of food for which he has a good appetite. He is now without pain as a rule. The heart's action is nearly normal, the bowels act with some regularity, as does the bladder, and his skin is of good color, acting well. There is no muscular atrophy.

P.S. I might add the strangest symptom of all, namely, that although the patient had been utterly helpless for so many years, about one and one-half years ago his wife gave birth to a good, big, healthy boy. Perhaps some of the brethren may attempt to explain it.

PTOMAIN POISONING FROM EATING CHEESE.

By G. LEO HAGEN BURGER, M.Sc., M.D., PH.D.,

HELENA, MONT.

BEING called by a father about 11:30 P.M. to see his family, especially two boys, three and six years old respectively, I found them prostrated, vomiting about thirty times during the interval of two hours, with a flushed head and face, cold extremities, rapid pulse, anxious countenance, cramped muscles of the legs, rigid and hard abdominal walls. The temperature was normal in one, 104° F. in the other. The vomit presented the appearance of finely divided particles of food, cheese, and portions of an apple eaten in the afternoon, several hours before supper-time, when the cheese was eaten by the whole family, including the two boys mentioned. The vomiting set in several hours after ingestion and rapidly increased, being accompanied by the above-related symptoms. A stimulant hypodermic of strychnine, morphine, and camphor was given, and the stomach washed out with a warm antiseptic solution, repeated several times in two hours. Hot sheets were wrapped about them, and over the epigastric region mustard pads were applied. Hot broths only were given for several days. During this time the little fellows had sufficiently recovered to be up and about the room. Now having learned of the eating of the cheese previous to the vomiting, and reasoning from the symptoms presented, I made a diagnosis of ptomain poisoning due to toxalbumins. Therefore specimens of the vomit, cheese, and diarrhœal discharge were collected, and an examination was made of each. Remembering the experiments of Husemann and Fleishmann I proceeded to examine the vomit for copper and zinc sulphate which is sometimes added in the centrifugal machines, to prevent heaving, as the dairymen call it. The result proved negative. No poison could be found except an amount of fatty acid which gave the cheese a strongly acid reaction, identical with the so-called German sausage poison, of which I had examined a number of specimens while in the health department in New York.

I have previously examined cheese, both with the microscope and chemically, without finding any cause whatever for the physiological effects and disturbances produced when eaten. The sample was rich in fats and proteids; its taste had nothing unusual about it, yet when eaten it caused vomiting and purging and made the consumer ill. Some was given to several kittens and to several dogs, with the result that two of the kittens were very ill, one in spasms the first time, from which she recovered; the second time, about a week afterward, the cheese had absolutely no effect on the same animal, but made the other one vomit and seem quite ill and depressed for four or five hours; it refused all food for several days. To one dog large draughts of water were given to see whether the water and the excessive amount of gastric juice and the acidity characteristic in the canine would have a modifying effect upon the poisonous substance or bacteria. The dog seemed to enjoy being fed with cheese until our supply was exhausted, and remained well. The second dog, which had no water, presented vomiting and retching for hours, abdominal pain, purging for

several days, and paralysis of the posterior extremities, leading me to think that perhaps lead or tinfoil used in packing the cheese had permeated the crust and that lead poisoning was present; but my mistake was soon apparent after testing the specimen. A small quantity of substance given off was precipitated by an alkali, soluble in a few drops of ether, and on adding platinum chloride a yellowish flocculent precipitate resulted, indicating an alkaloid similar to that which is found in ripened cheese undergoing putrefying process. Of the chemical nature of this pyrotoxin we know very little as yet, although intense symptoms of toxæmia ensue if it is ingested. It is frequently found in oysters, milk, and cheese. The urine was dark and high-colored; the fæces contained nothing abnormal save undigested fat, the diet of the boys being largely milk, and the bacterium coli commune and bacterium lactis aerogenes.

Surgical Suggestions.

Contraindications to the Use of the Decinormal Salt Solution may be summed up as follows: Atheroma, arteriosclerosis, cardiac degeneration, bad valvular disease, and recent cerebral apoplexy.—Dr. Ed. Smith, *American Practitioner and News*, October.

Conservative Operations on Ovaries and Tubes.—It is advisable to do conservative operations in all cases in which the ovaries and the tubes are not hopelessly diseased in all parts of their structure, except on patients who are near the menopause, on patients who have pronounced gonorrhœa of long standing, and on the rare cases of malignant disase.—Burroge.

Ingrowing Toe-Nail.—Remove all pressure from the nail by cutting away a piece of the shoe. Disinfect with hydrogen dioxide until no more "foam" appears. Apply a drop of strong solution of cocaine to the base of the ulcer. Apply a drop of Monsell's solution to the ulcer, then cover loosely with gauze. Repeat this process every second day until the edge of the nail is released by the retraction of the hypertrophied tissue.—Kinsman.

Prognosis of Dislocations at the Shoulder.—Don't be too quick to promise a perfect result after dislocation at the shoulder. The circumflex nerve passes closely around the surgical neck of the humerus, and often takes serious and lasting offence at the traumatism. Paralysis of the deltoid prevents abduction of the arm, permits gradual elongation of the capsular ligament, and recovery from it is usually slow and incomplete; hence the wisdom of a lagging prognosis.—William V. Morgan.

Cancer of the Uterus.—Total extirpation of the uterus should be practised in all cases of cancerous lesions of the uterus of whatsoever part, for this procedure gives the maximum guarantee against the return. Total extirpation of the uterus through the vagina deserves the preference over the other methods.—Demitri De Ott, of St. Petersburg.

Wounds of Veins are of importance both on account of the immediate and the remote effects they produce. The immediate troubles which have to be dealt with are (*a*) dangerous hemorrhage and (*b*) entry of air into the vein. The remote troubles are chiefly thrombosis, embolism, pyæmia, and œdema of the part corresponding to the distribution of the vein. The immediate troubles are more common in connection with operation wounds, the remote troubles in accidental wounds.—Cheyne and Burghard.

Cervical Metritis.—It is necessary neither to consider nor to treat cervical metritis as an isolated affection, since the greater number of cases are complicated by a similar affection of the fundus. The term "cervical metritis" should in the majority of cases be replaced by that of cervical endometritis, since the inflammation of the mucosa is only rarely accompanied by a lesion of the deeper tissues.—Mendes de Leon, of Amsterdam.

Mouth and Pharynx Wash.—

℞ Acid. benzoic..... 3.
Tinct. eucalypt..... 15.
Alcoholis..... 100.
Ol. menth. pip 0.75
M. S. Add enough to half a wineglassful of water to produce distinct clouding. Hold in mouth for one minute.

—Warren.

Tuberculosis of the Testis.—Early castration has returned to favor and is justified on the following grounds: 1. It is the most speedy form of treatment for this local tuberculosis. 2. It is a rapid treatment, which avoids pulmonary and meningeal complications. 3. It prevents the spread of tuberculosis to the genital tract of the opposite side. 4. It causes a recession of the concomitant vesiculo-prostatic lesions.—R. Baudet.

A New Injection Treatment for Bone Tuberculosis.—

℞ Sodii sulphuret..... 1.46
Sodii chloratis..... 16.40
Sodii phosphat..... 0.50
Sodii carbonat..... 0.70
Potass. sulphuret 0 94
Aq. destill 80.0
M.

This fluid is injected into the sinuses by means of a cannula attached to a Pravaz syringe. The sinuses are distended with the fluid, which is injected until a reflow occurs. After all the sinuses are thus cauterized a ten-per-cent. iodoform-ether injection is made, and a moist Priessnitz applied.—C. Trunecek.

Vasectomy for Enlarged Prostate.—Reginald Harrison, F.R.C.S., in the *Medical Fortnightly*, May, deduces the following conclusions: (1) That vasectomy has been shown to be specially effectual in the earlier stages of prostatic enlargement in effecting shrinkage of the gland and the restoration of the natural process of micturition. (2) That in cases in which there is evidence to show that the gland has in the course of degeneration assumed the form and structure of a fibrous growth the conditions are such, provided the symptoms of obstruction warrant the adoption of other measures than catheterism, as to render some form of prostatectomy preferable to either vasectomy or castration. (3) That when, as a consequence of sudden or protracted prostatic obstruction, secondary changes have taken place in the bladder itself, in the form of sacs, pouches, or trabeculation, the possibility of restoring its natural function by any means is extremely unlikely. Under such circumstances the induction of shrinkage of the enlarged gland will do good in affording a readier access for the catheter and in removing spasm, pain, or hemorrhage connected with this or other similar process.

Indications for Operation in Hernia.—Not every case of hernia requires operation. In reducible hernia, when the patient can wear a truss with comfort and without inconvenience to him, in the performance of his necessary duties, operation for hernia is superfluous. In irreducible hernia, an operation is usually indicated. The fact that the hernia is almost sure to increase in size, the pain and dragging, and weakness, associated with the presence of the hernia,

diminish the patient's ability for work, and become indications for operation. In obstructed and strangulated hernia operation is indicated and should be performed as soon as the diagnosis has been made. In children under four years of age, unless the hernia is strangulated, incarcerated, or irreducible, operation is to be avoided, for it has been found that a large proportion of these patients recover within the first three or four years by the application of a suitable truss.—CHARLES B. PARKER.

Stitch Abscesses.—Don't always blame your suture material whenever you get a so-called stitch abscess. The great majority of these are not at all due to the sutures, but to the fact that there has been an infection due to the existence of noxious organisms in the deeper cutaneous layers, which cannot always be removed by the most thorough and most conscientious scrubbing. Careful washing with green soap and alcohol, followed by a large wet dressing of bichloride applied the day before an operation, will greatly diminish the number of these generally miscalled stitch abscesses.—HOWARD LILIENTHAL.

Therapeutic Hints.

Flatulent Dyspepsia.—

℞ Magnesia,
Phosphate of lime,
Powd. charcoal,
Sulphur sublim.....āā 10
M. S. Teaspoonful in water as required.

Or—

℞ Olei creosoti..... ♏ xij.
Spir. tenuioris..... ʒ ss.
Ammonii benzoatis..... ʒ ij.
Glycerini..... ʒ vi.
Infusi caryophylli.....q.s. ad ʒ vi.
M. S. Teaspoonful in water.

—RICHARDSON.

Hemorrhoids.—

℞ Vaseline..... ʒ i.
Muriate of cocaine..... gr. xij.
Morphine..... gr. vi.
Calomel..... gr. xl.
M. S. Apply locally night and morning. If itching is severe apply menthol, one drachm to an ounce of vaseline.

—JOSEPH M. MATTHEWS.

Prostatic Disease.—

℞ Tr. aconite..... ʒ i.
Tr. gelsemium..... ʒ ij.
Antipyrin..... ʒ ij.
Ergotol..... ʒ i.
Water.....q.s. ad ʒ iv.
M. S. Give a dessertspoonful in a wineglass of water every one, two, or three hours.

—EUGENE R. CORSON.

Spray for a Room Occupied by a Consumptive.—Free ventilation should be used in addition.

℞ Guaiacol..... ʒ ij.
Eucalyptol..... ʒ ij.
Menthol..... ʒ i.
Thymol..... ʒ ss.
Ol. gaulther..... ʒ vij.
Ol. menthæ pip.....q. s. ad fl. ʒ i.

—DR. O. F. BAERENS, *Regular Medical Visitor*, October 15th.

Cerebro-Spinal Fever.—In the treatment of cerebro-spinal fever, as in so many other diseases, various remedial agents are lauded, but until the value of something new has been more clearly demonstrated, good nursing, easily assimilable nutriment in plenty, a quiet and darkened room for the patient, intelligent hydrotherapy, and the bromide of potassium will be, it seems to me, our mainstays.—DR. F. B. MAYNARD, *Albany Medical Annals*, November.

Dysentery.—

℞ Potass. et sod. tart., sat. sol..... ʒ ij.
Tinct. opii. camph..... ʒ ss.
Syr. rhei aromat.....q.s. ad ʒ iv.
M. S. Two teaspoonfuls every hour.

This should be given until two or three evacuations are produced. In later stages, when there is much blood and tenesmus, a suppository is recommended of

℞ Ext. opii..... gr. i.
Ext. hyoscyami..... gr. ij.
Ext. belladonnæ..... gr. ½

to be repeated if necessary.—R. B. HOPKINS.

Nutritive Enemata after Abdominal Section.—

℞ Peptonized milk..... 30 c.c.
Whiskey..... 30 "
The whites of two eggs.
Common table salt..... gr. xxiv.

The rectum should be thoroughly irrigated every morning with warm physiological salt solution, which will keep it clean so that the nutritive enemata will be better absorbed.—HUNTER ROBB.

Indications for the Use of Lavage.—(1) To remove undigested food and foreign matters; (2) to cleanse the mucous membrane for the action of medicines; (3) to check hemorrhage; (4) to give antiseptic douchings; (5) for sedative purposes; (6) for general tonic effects upon the gastric mucous membrane and parietes.—DR. J. M. G. CARTER, *Medical Fortnightly*, October 10th.

Reflex Vomiting in Children.—

℞ Olei absinthii..... gtt. ½
Sodii bicarb..... gr. ij.
Aq. menthæ piperitæ..... ʒ i.
S. Every half-hour until relieved.

—DILLON BROWN.

Dysentery.—

℞ Olei ricini..... ʒ i.
Tincturæ ipecacuanhuæ comp..... ʒ ij.
Sacchar. albæ..... ʒ ij.
Pulveris acaciæ..... ʒ iij.
Aquæ menth.....q.s. ad ʒ iv.
M. S. A teaspoonful every two to three hours when the case is first seen.

This tends to relieve the irritability of the inflamed bowel and carries away the concretions of fæces.—E. H. BAYLEY, *Medical Dial*, October 10th.

Condylomata.—

℞ Calomel..... 30 parts.
Boric acid..... 18 "
Salicylic acid..... 5 "
S. Apply three times a day.

—*Gazette Hebdomadaire de Médecine et de Chirurgie*, July 22d.

Lobar Pneumonia.—Pain is the most prominent symptom, and the relief of it is important. The most rational thing to do is to immobilize that side of the chest and apply warm, soothing poultices. If necessary, a small amount of morphine may be allowed. The treatment is practically expectant, but the following may be allowed in some cases:

℞ Tincturæ aconiti..... ♏ i.
Tincturæ digitalis..... ♏ iij.
Spiritus frumenti..... ʒ iij.
S. This is to be taken every three hours.

—LOUIS F. BISHOP, *The Medical Times*, October.

Hiccup.—Even in cases of the gravest organic lesion, it is sometimes possible to relieve the symptom by some of the following methods: (1) Holding the breath for fifteen or more seconds; (2) administration of quick-acting emetics (though too great depression from these must be thought of), or peristaltic stimulants; (3) hot applications over the cervical

spine and diaphragmatic area; (4) firm pressure upon the phrenic nerve over the scalenus anticus muscle; (5) rapid swallowing of small pieces of ice; (6) the use of such antispasmodic drugs as morphine, or chloroform, in full dosage (the bromides, camphor, belladonna, valerianates, antacids, and musk have been advocated, but are commonly too slow in action for severe cases); (7) traction on the tongue, intermittently applied, as in chloroform poisoning; (8) galvanization of the phrenic nerve; (9) faradization of the epigastric region (Erb); (10) forcible elevation of the hyoid bone by the attendant's fingers (Nothnagel); (11) the method described by Kingscote, in his work on asthma, 1899.—*The Medical World*, November.

Carbonic Acid.—In an article on the "Carbonic Acid Aerostat" (*Journal of Surgical Technology*, August) Dr. A. Rose sums up as follows: Carbonic-acid gas exerts a feeble antiseptic action and also an anæsthetic action, especially upon mucous membranes. It exercises a stimulant action on the enfeebled heart. By the operation of the law of the diffusion of gases it increases the amount of oxygen in the pulmonary alveoli. It relieves dyspnœa and cough, and disembarrasses the respiration. It stimulates ulcerated surfaces to healthy processes of repair; while for diagnostic purposes it forms an easily available method of inflating the cavities of the body.

Variola.—The treatment of variola is based upon the same scientific principles that dictate the rational treatment of all other pathological processes going on in the human system. It consists in sterilizing, so far as possible, the invading microbe, sustaining the vital force with all the necessary food, and in keeping all of the secretions and excretions as near normal as possible.—E. E. Gilmore, *Kansas City Medical Record*, September.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 10, 1900:

	Cases.	Deaths.
Tuberculosis	250	159
Typhoid fever	90	27
Scarlet fever	93	4
Measles	45	0
Diphtheria	212	27
Laryngeal diphtheria (croup)	11	7
Cerebro-spinal meningitis	0	6
Varicella	15	0
Smallpox	1	0

Meningitis Complicating Pneumonia, with Recovery.—Dr. T. C. Ely (Pennsylvania *Medical Journal*, October) reports a case of meningitis complicating pneumonia, with recovery; the points of more than usual interest he summarized as follows: (1) The recovery from pneumonia complicated by meningitis, a rare issue. (2) The striking clinical resemblance to cerebro-spinal fever in its late phenomena, which calls forth the query whether lumbar puncture is absolutely essential to differentiate such cases or whether the clinical history is not sufficient. (3) The mixed form of pneumonia, of croupous type, becoming lobular; a pneumonia which might have terminated by crisis as a croupous form had not pyogenic organisms co-operated in a soil likely tuberculous. (4) The family history, personal history, and some aspects of the clinical course point to tuberculous meningitis, which, contrary to the general belief, ended in recovery. This leads to the question, May not some local cases of tuberculous meningitis terminate favorably, just as local tuberculosis in other parts of the body may heal? (5) In any case on account of the uncertainty of diagnosis of tuberculous meningitis, the scientific inaccuracy of calling a case tuberculous meningitis because it terminates fatally, or some other form of meningitis because there is recovery, is open to criticism. (6) No case of meningitis should be despaired of simply because there is a suspicion of tuberculous infection.

Fracture of the Spine.—Dr. Walter Lathrop, in the Pennsylvania *Medical Journal*, October, summarizes an article on this subject as follows: (1) In partial lesions we should operate. (2) When the lumbar region is involved, with lesions of the cauda equina, operation offers the best chance for recovery. (3) In fracture of the spinous process, lamina, or entire neural arch, operation is demanded. (4) Should immediate operation not be done, and we wait six to eight weeks, with the result that paralysis of the bladder and bowels continues, with cystitis and severe bed sores present, we may be sure that nature cannot relieve the case, and an operation is not only indicated, but demanded.

Gingivo-Stomatitis with Albuminuria.—Dr. Charles Lee, in the *British Dental Journal*, September, concludes an interesting article on this subject as follows: (1) Ulcerative membranous stomatitis in patients suffering from Bright's disease is a polymicrobic septic stomatitis which may be classed with the variety of septic stomatitis described by Dr. Lebedinsky; (2) such a stomatitis may pass through various conditions; it may be erythematous, then ulcero-membranous, or even gangrenous; (3) the stomatitis of albuminuria commences almost always on a level with carious teeth or infected stumps; (4) those who are suffering from albuminuria may safely avoid stomatitis if their mouths are kept in a hygienic condition.

Physical Training—its Range of Usefulness in Therapeutics.—Dr. B. E. McKenzie, in the *Canadian Journal of Medicine and Surgery*, November, summarizes briefly as follows: (1) Special physical training is rendered necessary for the young by the conditions of modern life. (2) The work is made special and scientific, having for its object the development and strengthening of every organ and faculty of the patient. (3) As we conduct this work it is mainly educative. Force from without the patient, however, is largely employed with such as cannot of their own volition correct the deformity. To name the affections benefited in the order in which good results have been observed I would place them thus: Hysteria, roto-lateral curvature, flat foot, round shoulders, pigeon-breast, flat chest, anæmia, paretic weakness, chorea, imbecility. In this list I have placed hysteria first, because I have not known any method by which this condition, generally so unsatisfactory to deal with, has been brought so successfully under control.

The Operative Treatment of Complete Prolapse of the Uterus in Elderly Women.—Dr. A. Lapthorn Smith, in the *Maritime Medical News*, October, comes to the following conclusions: (1) That a woman suffering from procidentia or prolapse of the uterus out of the body, though not in much pain, is yet very miserable. (2) She is in some danger, owing to the cervix becoming ulcerated and the ulceration frequently becoming cancerous. (3) It is a mistake to think

that she is too old to undergo an operation because she is forty-five, or fifty, or even seventy-five years of age. (4) Elderly women support the operations remarkably well; the operations require only from twenty to thirty minutes for performance; and even if we knew that the patients were going to live only a year afterward, it would be well worth while operating for the sake of the comfort it affords them. (5) The operation of vaginal hysterectomy is especially easy and safe in these cases, having not more than one per cent. of mortality and probably not even that. (6) Ventrofixation gives good results when the uterus is short, but fails when it is long. In some cases the vagina and bladder pull down and elongate the cervix after the fundus has been firmly attached to the abdominal wall. (7) In either case, whether hysterectomy or ventrofixation be employed, it should always be followed by an anterior and posterior colporrhaphy. (8) These patients should remain in bed for six weeks after their operation, in order to give time for the new tissue to become strong.

Tertian Æstivo-Autumnal Parasite and the Quotidian Parasite.—The tertian æstivo-autumnal parasite differs from the quotidian parasite in the following particulars: (1) During the hyaline stage—the rings are larger, being from one-eighth to one-fourth the size of the infected corpuscle; the signet-ring shape; the sluggish amœboid motion; the clear-cut and refractive outline; the less wrinkled and lighter green infected corpuscle; the occurrence of only one parasite in the infected corpuscle. (2) During the pigmented stage—the larger size, one-half of the corpuscle; the pigment ring forms; the continuance of amœboid motion; more sharply defined and refractive, and the granular protoplasm; the finely granular pigment, which is motile; the occurrence of only one parasite in a corpuscle, and the lighter-colored, seldom crenated infected corpuscle. (3) During the segmenting stage—the occurrence of segmentation outside the corpuscle; the number of segments, ten to fifteen. (4) The larger, more narrow, more deeply pigmented crescents seldom showing a double outline. (5) The cycle of development, forty-eight hours.—Dr. Charles F. Craig, in *Journal of the Amer. Med. Ass'n*, November 3, 1900.

Spinal Anæsthesia.—I would limit the indications for its applications at the present moment: (1) To adults, and to reasonable persons who have good self-control, thereby excluding children, hysterical patients, and the insane; (2) to patients in whom the methods of local or regional anæsthesia are inapplicable; (3) to patients suffering from emphysema, advanced asthma, chronic bronchitis, and other respiratory affections in whom a general inhalation anæsthetic is absolutely contraindicated; in advanced cardiac cases with degenerative lesions, I would fear the possible depressing effects of the injection and excitement on the circulation. (4) In the majority of cases in which the painful part of the operation is not likely to be prolonged beyond one hour and a half, as I would be averse, in the present state of our knowledge, to repeat a second cocainization or to increase the total dose of the cocaine to more than 2 c.c., especially in exhausted subjects. — Dr. Rudolph Matas, in the *Phila. Med. Journal*, November 3, 1900.

Interstitial Keratitis.—The points that require emphasizing are: (1) That treatment supports the belief, now almost universal, that interstitial keratitis in childhood is a manifestation of hereditary syphilis; (2) that it may be the only recognizable manifestation of the hereditary taint, though other well-known manifestations are often present as well; (3) that prolonged constitutional treatment is necessary to obtain a satisfactory result—the result being nearly, if not always, satisfactory if constitutional treatment is thorough and prolonged; (4) that constitutional treatment by mercury is not only very well borne but the general health is improved under it; (5) that the second eye may begin to have an attack, and even proceed to have a severe one in spite of the fact that the system has been for months under the influence of mercury, which has, indeed, been the cause of the recovery of the eye first attacked as well as of increased bodily health, and which will, if persevered in, cause the recovery of the second eye also.—Dr. J. Lockhart Gibson, in *The Australasian Med. Gazette*, September 20, 1900.

Papilloma of the Larynx in Children.—Dr. Edward T. Dickerman, in the *Journal of the American Medical Association*, October 27, 1900, offers the following conclusions in an article on this subject: (1) That papilloma of the larynx is, especially in this country, a rare disease; (2) in a number of cases papillomata undergo spontaneous cure; (3) intralaryngeal methods should always be tried first, unless dyspnœa is pronounced, when tracheotomy should be done at once; (4) after tracheotomy, intralaryngeal methods should be tried; (5) patients should wear a tube six months after the growth has disappeared; (6) thyrotomy should be considered only as a last resort.

A Few Points on Appendicitis.—Dr. J. Henry Barbat, in the *Journal of the American Medical Association*, October 27, 1900, concludes as follows: (1) That over ninety per cent. of cases of true appendicitis which are not operated on have recurrences; (2) that we should operate on all cases of chronic recurrent appendicitis, if possible between attacks; (3) that in practically all cases which end fatally after operation we find at least forty-eight hours between the onset of the attack and the time of operation, therefore it is reasonable to assume that if these cases had been operated upon inside of the forty-eight hours the patients would have been cured; (4) that as soon as a diagnosis of acute appendicitis is made, we should operate immediately; (5) pulse and temperature are not to be taken into consideration in making a diagnosis of appendicitis; (6) in acute cases the diagnosis must be based on the symptoms which were manifested during the first three or four hours.

Cancer of the Uterus and its Treatment.—Dr. Stansbury Sutton, in the *International Journal of Surgery*, November, states his views from the standpoint of a mathematical problem as follows: Given one hundred cases of uterine cancer treated by vaginal hysterectomy; result, four deaths, ninety-six recoveries. Credit the latter with an average of two years of life after the operation; thus we have the result: gain in human life, one hundred and ninety-two years. Given the same one hundred cases subjected to vaginal hysterectomy from two to three years earlier, prior to the advent of cancer; result, deaths, four: recoveries, ninety-six. Credit the latter with an average of ten years of life after the operation; thus we have the result: a gain of nine hundred and sixty years of human life. Take the difference in these results, viz., seven hundred and sixty-eight years of human life, in favor of prophylactic operating, viz., operating before cancer has become installed.

Gall-Bladder Surgery.—Dr. A. Vander Veer in the *International Journal of Surgery*, November, makes the following final conclusions: (1) An early diagnosis of cases. (2) In suppuration of the bladder, with adhesions, a most thorough examination should be made from within by digital exploration, and the use of the probe for any possible deep-seated calculi. (3)

In prolonged operations upon the common duct or hepatic ducts, when adhesions are present and it is difficult to close the incision after removal of the calculus, drainage through the peritoneal pouch, by means of the lumbar stab, is advisable. (4) When the patient is suffering seriously from cholæmia, with marked ecchymotic spots over the body, intense itching, and an examination of the blood discloses a septic condition, an operation is not to be encouraged. It is too late, in the vast majority of cases, for the patient to recover. (5) General practitioners, as well as the surgeon, should place more earnestly before the patient and friends the dangers of repeated attacks of gall-stone irritation resulting in cancer of the ducts, stomach, or liver.

Tuberculous Lesions from a Clinical Point of View.—Edmund Owen, M.B., F.R.C.S., in the *Canada Medical Record*, September, makes the following statements: "(1) Chronic inflammation of a joint in a child or young person is always tuberculous—except in those very rare cases in which it is due to hereditary syphilis or osteo-arthritis. (2) Tuberculous inflammation may completely destroy a joint, and then leave it solidly and soundly synostosed, without the surrounding tissues or the skin having been implicated. (3) If tuberculous granulation tissue breaks down into a fluid, that fluid is not pus, and the collection is not, properly speaking, an abscess—unless, by bad fortune or by worse surgery, it has become infected by septic micro-organisms. (4) The fluid collection is not to be treated as an abscess—by incision and drainage, that is—but is to be opened and emptied and scraped and cleansed of its unhealthy lining of granulation tissue. Then the wound in the skin is to be completely closed by sutures; firm pressure is to be evenly applied and the part is to be kept absolutely at rest. It is no news to most of you to be told that the success attending this line of treatment leaves, as a rule, little to be desired, or that for this important advance in practical surgery we are chiefly indebted to the patient researches of our friends with the smock-frocks and the guinea-pigs. (5) I have failed to discover that iodoform is of any peculiar value in the treatment of tuberculous lesions. At any rate I have long since discarded it, and I have not noticed any falling off in the results of my practice in consequence. Iodoform is an irritant and a poison; it is apt to be septic, as germs can grow upon it, but I have no knowledge of the truth of the statement that mushrooms have actually been cultivated on it."

Field Hospitals in War.—Mr. Frederick Treves, who we understand will shortly publish a book upon ambulances, the subject-matter of which will have been gathered from his experiences in South Africa, read a paper at the late meeting of the British Medical Association treating of army medical matters in general. He said that the South African campaign had shown the value of a large mobile field hospital (taking three hundred to six hundred patients), which should immediately follow the colors; such a hospital to have its own transport. The campaign had also demonstrated the fact that the field hospital was no place for the female nurse, but that in the base hospitals they might be increased with advantage. When nurses were lacking, the orderly had to take their places, and he is an almost impossible person. He had to do manual labor as pitching tents, digging trenches, and then nurse complicated cases. Mr. Treves also urged the formation of an army medical reserve, by inducing recently qualified medical men to agree to serve for three years, one with the colors and two with the reserve. This reserve would be called upon only in time of war, and would enable the army medical department to avail itself of a body of specially trained medical men, who, from its point of view, would have the advantage of an army training. He was of the opinion that the services of men thus trained would be more valuable than those of a number of civilian surgeons chosen more or less irrespective of their qualifications. Mr. Treves' plan might commend itself to the adoption of our military authorities.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended November 9, 1900:

		Cases.	Deaths.
Smallpox—United States.			
Colorado, Arapahoe Co.	October 13th to 25th	5	
Elber Co.	October 19th	1	
Saguache Co.	October 14th	1	
District of Columbia, Washington	November 3d	1	
Kansas, Wichita	October 27th to November 3d	3	
Kentucky, Lexington	October 27th to November 3d	2	
Louisiana, New Orleans	October 27th to November 3d	2	
Massachusetts, Taunton	October 27th to November 3d	1	
Michigan, Detroit	October 27th to November 3d	1	
Ohio, Cleveland	October 28th to November 3d	1	
Oregon, Portland	October 31st	1	
South Dakota, Sioux Falls	Six months ended October 31st	1	
Utah, Salt Lake City	October 27th to November 3d	5	
Tennessee, Memphis	October 27th to November 3d	1	
Smallpox—Foreign.			
Bohemia, Prague	October 13th to 20th	2	
England, Liverpool	October 13th to 20th	2	
West Hartlepool	October 13th to 20th	1	
France, Paris	October 13th to 20th	..	11

ON APPARENT TUMORS OF THE ABDOMEN.*

BY MAX EINHORN, M.D.,

PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL, NEW YORK.

ABOUT two years ago I had the opportunity to present to the Society of Physicians of the German Hospital and Dispensary of New York a patient with a tumor in the epigastric region, that could be distinctly and plainly palpated. I remarked at the time that, in spite of the resistance which could be easily felt, we did not have to deal with a possible neoplasm, but that a somewhat abnormal position of the abdominal viscera was the cause of this deceptive tumor.

Now, gentlemen, these cases of apparent tumors as they may be called—*i.e.*, tumors easily palpated, not caused by real neoplasms, however, but by an abnormal position of the abdominal viscera or an abnormal condition of parts of the abdominal muscles—are not so very rare, and it would perhaps be of interest to investigate them a little more closely. We do not find much in medical literature upon this subject.

Da Costa[1] says in his book on "Medical Diagnosis," p. 653: "The muscular contractions are not always confined to one muscle, or to the whole of one muscle, and when irregular, and particularly when associated with tympanitic distention of the intestine, give rise to most of the so-called 'phantom tumors' of the abdomen. These swellings are perplexing and are constantly mistaken for serious abdominal tumors. The history of the case, the absence of grave constitutional symptoms, the most frequent occurrence of the tumefaction in females, especially in hysterical females, and the usually coexisting constipation, furnish us with valuable signs of distinction."

Potain[2] has accurately described a case of phantom tumor caused by an anomaly of the abdominal muscles. In connection with this subject he has called attention to the faulty conclusions that may be arrived at as the result of palpation of the abdomen. He expresses himself as follows: "The abdominal wall seems to be specially adapted for examination by palpation, but auscultation, which in the study of thoracic affections renders us such great services, fails us altogether in the recognition of diseases of the abdominal organs, whose functions are performed silently. Moreover, palpation, which usually teaches us so much, may at times give rise to singular illusions; and among all the errors, liable to be thus made, none are perhaps more frequent than those caused by phantom tumors (fausses tumeurs) of the abdomen."

Santovecchi[3] describes the case of a young, nervous girl, who was suffering from a swelling in the right hypochondrium that was looked upon as a tumor of the liver, or the gall bladder, or the pylorus, or the omentum. Since the tumefaction caused a good deal of pain to the patient, and as she readily consented to an operation, an exploratory incision under anæsthesia was made. No tumor was, however, found, all the organs being in normal condition. As far as the subjective symptoms were concerned, the result of the operation was a very good one. Santovecchi explains this apparent tumor by a spasmodic contraction of the abdominal muscles.

Whereas in the cases just cited the apparent tumors were caused by the abdominal muscles, the tumefaction in a case described by Brault and Rouger[4] was caused by a prolapsed liver. The diagnosis was, however, made only after a laparotomy.

Bertrand,[5] cited by Brault and Rouger, in the year 1896 collected from literature twenty cases of phantom tumors.

Glénard[6] frequently mentions in his well-known work, "Ptoses Viscérales," that the impression of the presence of a tumor, caused either by an anomaly of the abdominal muscles or by the "corde colique transverse," may be gained in some cases of enteroptosis. He says: "There are patients in whom the exaggerated sensitiveness of an underlying organ provokes, at the approach of the hand, a contracture of the abdominal muscles; this is especially observed in the right rectus muscle near its costal attachment. One would suspect with such patients that the left lobe of the liver is the seat of some inflammation or congestion; the muscle contracts to protect the organ from the pain which pressure would produce. This is another variety of what have been called 'phantom tumors' of the abdomen." He does not, however, enter further upon a differential diagnosis.

The apparent tumors which form the subject of this paper do not include cases of swellings caused by a prolapse of the whole liver, kidneys, or spleen. Kidneys and spleen, owing to their characteristic shape, are nowadays hardly ever confounded with tumors. A prolapsed liver might more easily give rise to an erroneous diagnosis. This, nevertheless, may also be avoided if the occurrence of movable liver is kept in mind. The apparent tumors which I will speak of here relate to swellings found either directly in the epigastrium or the left or right hypochondrium, and have nothing to do with a neoplasm of whatever kind. (I have purposely avoided the expression "phantom tumor," as the latter is usually applied to tumefactions occurring principally in the lower part of the abdomen in hysterical subjects, and caused by a high degree of meteorism. With these our cases have nothing in common.)

In most cases of this kind a resistance may be detected by palpation, sometimes even by inspection, lying between the ensiform process and the umbilicus, presenting a rather smooth surface and frequently pulsating. The size of these tumefactions varies between that of a hen's egg and a man's fist. Light percussion always elicits a dull sound over the area of resistance.

These apparent tumors are not exactly of frequent occurrence. I have collected the cases ob-

*Read before the German Medical Society of New York, October 1, 1900.

served by me since 1897, and have tabulated them as follows:

TABLE OF THE TOTAL NUMBER OF CASES OF APPARENT TUMOR, OBSERVED BY ME FROM 1897 TO SEPTEMBER, 1900.

Year.	Total Number of Patients.	Males	Females	Total Number of Apparent Tumors.	Apparent Tumors.	
					Males	Females
1897.....	1,430	835	604	8	3	5
1898.....	1,447	872	575	12	3	9
1899.....	1,741	1,006	735	11	2	9
1900 (till Sept. 11th)	1,418	809	609	11	..	11
Totals...	6,045	3,522	2,523	42	8	34

Out of 6,045 patients, therefore, there were 42 cases of apparent tumor, 8 occurring in men and 34 in women. Expressed in percentages the total number of cases of apparent tumors was 0.69 per cent. of persons suffering from digestive disturbances. Of these the men constitute 0.23 per cent. and the women 1.35 per cent. of all cases. As an example I will now relate the histories of a few characteristic cases of this kind, tabulating the rest of the cases.

CASE I.—July 14, 1899. Mrs. R. W——, thirty-five years of age, has for the last three years been a great sufferer from digestive disturbances. She complained principally of slight pains in the epigastrium, occurring about one-half hour after eating and lasting two to three hours. In the beginning the appetite was good. The patient was much troubled with eructations. The bowels were generally sluggish. About two years ago she became worse. The pains increased in severity and used to occur immediately after eating. She now began to vomit, but never threw up blood. Her physician at that time made the diagnosis of ulcer of the stomach, and the patient was put on a strict diet, extending over six weeks. She recuperated very slowly, but never was altogether free from pain in the region of the stomach. About two months after her treatment for ulcer she was able to take light food and to attend to her domestic duties. Her appetite at this time was capricious, her bowels were constipated, her sleep was restless, and her digestion was accompanied by disagreeable sensations in the abdomen. The patient remained in this condition until about May, 1899, when a turn for the worse took place. Again vomiting occurred immediately after meals, associated with rather intense pains in the region of the stomach. She could not take sufficient food and began to lose in weight. A chemical examination of the stomach, undertaken by her physician, showed a high degree of hyperchlorhydria. The usual method of treatment for this condition (alkalies) remained, however, without appreciable results, and the patient had to take considerable doses of morphine daily. In this condition she remained until she consulted me in July, 1899. She then told me that during her last illness she lost twenty pounds. Her physician, who was kind enough to direct the patient to me, sent her to me with the diagnosis of a probable carcinoma of the stomach on the basis of an ulcer.

Status præsens: The patient is of slender stature, looks somewhat emaciated and anæmic. Her tongue is slightly coated. The thoracic organs are intact. Inspection of the abdomen reveals a slight protrusion of the size of a hen's egg lying in the linea alba at the beginning of the second third, between the ensiform process and umbilicus (Fig. 1). On palpation the epigastrium is rather sensitive to pressure. At the place described a resistance may be felt which has quite a smooth surface and is slightly dull on percussion. The position of the stomach can easily be made out by the splashing sound. The stomach reaches about a hand's width below the umbilicus. Transillumination also shows a high degree of gastroptosis. The area of transillumination of the stomach extends from about two fingers above the navel to about a hand's width below it. The protrusion (resistance) described above, lies about 4–5 cm. above the small curvature of the stomach. The patellar reflexes are present. The urine is free from albumin or sugar. The examination of the stomach one hour after Ewald's test breakfast shows HCl + = 48; T. Ac. = 68. In the fasting condition the stomach is empty.

A diagnosis of gastroptosis, hyperchlorhydria, and probably old ulcer of the stomach was made. A carcinoma was excluded with great probability, as the protrusion lay above the stomach and presented quite a smooth surface.

As I was unable to confirm the probable diagnosis of carcinoma made by the physician in charge, the latter was very much dissatisfied with my opinion, and wrote me a letter to that effect. A year later, however, the patient was in a much better condition than when she first came to me. It is therefore safe to assume that carcinoma was not present.

CASE II.—April 8, 1898. Dr. F. D. A——, physician, forty years of age, has been suffering for a year from rather severe digestive disturbances. At first he used to complain of slight pains in the stomach one and a half hours after eating, together with frequent eructations of gas and at times regurgitation of a strongly acid fluid. Constipation was present in a high degree. Later a material loss of appetite developed and the pains in his stomach began to appear earlier (about one-half hour after eating). He began to lose steadily in weight, became weaker, and was unable to attend to his professional duties. The patient consulted several physicians, who all declared his trouble to be a very serious one. Carcinoma was universally suspected. A noted surgeon discovered a tumor in the gastric region and advised immediate operation. Before the patient followed this advice he concluded to get also my opinion. I found the following condition: A very much emaciated and cachectic-looking man with pale lips. Examination of the thoracic organs revealed nothing abnormal. On palpating the abdomen an oval resistance, of the size of a small hen's egg, was felt above the umbilicus, lying more to the right side (Fig. 2). It had a smooth surface, moved a little with respiration, and gave on slight percussion a dull sound. The stomach was quite large, the lower curvature reaching three fingers below the navel; a splashing sound could easily be elicited. The epigastrium was somewhat tender on pressure. The patellar reflexes were present. The urine contained neither albumin nor sugar.

The examination of the stomach one hour after Ewald's test breakfast gave the following results: The stomach contents consisted of a watery liquid containing only fine particles of roll. Other food remnants were not resent. HCl + Ac = 72.

Although the small tumor described above could be plainly felt I still remained in doubt about its nature, whether I had to deal with a real neoplasm, or an apparent tumor caused in this case principally by the abdominal muscles. I advised treatment suitable for a case of atony of the stomach with hyperchlorhydria. The patient received alkalies and was put upon a liberal diet. He improved visibly. Seven months later, on November 16th, he came to me again. He then looked strong and healthy, and told me that he had gained thirty-five pounds and had not been suffering lately from any digestive disturbances whatsoever. On examination of the abdomen, I found that the resistance which formerly could be easily felt had disappeared.

CASE III.—January 4, 1898. Mrs. J. P. B——,

about fifty-four years old, has suffered for about ten years from dyspeptic symptoms. Her appetite was at times capricious, her sleep was restless and disturbed by dreams, the bowels were inclined to be constipated, a slight feeling of oppression in the region of the stomach was felt at times shortly after eating, but none of these difficulties was of a serious nature. In 1897, however, the patient began to suffer from more pronounced symptoms. There was nearly total anorexia, and soon after every meal intense pains in the epigastrium developed. Associated with this was vomiting; the latter, however, occurred only occasionally (once in eight to fourteen days). The patient was treated by several able colleagues, and was put on a strict diet. At first she lived on an exclusive meat diet for several weeks. As this mode of treatment was not crowned with success, she was put upon a strict milk diet. But even this does not seem to have exerted any favorable influence. The patient lost constantly in weight. During the last five to six months she had been on the following diet: Breakfast: Two pieces (30 gm.) of toast and a cup of clear, weak tea. Lunch: Extract of one pound of meat, three pieces (45 gm.) of toast, clear tea; only one of the pieces of toast buttered (5 gm.). Dinner: Same as lunch. I purposely give the amount and kind of food according to the patient's statement. The amount of food taken in twenty-four hours contained six hundred and nineteen calories. No wonder that considerable subnutrition resulted. When the patient came to me she stated that she had lost fifty pounds during the last year. She complained of a feeling of extreme weakness, dryness of the mouth, vertigo, intense pains after the slightest amount of food taken, and obstinate constipation.

Status præsens: A tall, stately woman; is emaciated in the highest degree. The skin over the arms can be lifted in large folds. The color of the lips and cheeks is pale. The tongue is much coated. Except for a slight presystolic murmur at the apex of the heart the thoracic organs are normal. Examination of the abdomen reveals considerable pain on pressure over the epigastrium. The large curvature of the stomach reaches nearly to the os pubis, whereas the smaller curvature lies somewhat above the umbilicus. A splashing sound can easily be produced in the stomach. The right kidney can be palpated in its entirety and is movable in the fourth degree. Two fingers below the ensiform process, in the epigastric region, a prominence of the size of an apple can be demonstrated (Fig. 3). It has a smooth surface. The generative organs show nothing abnormal. The patellar reflexes are present, and the urine contains neither albumin nor sugar. Examination of the stomach one hour after Ewald's test breakfast shows the presence of free HCl and the absence of food particles from the day previous. A diagnosis of enteroptosis and apparent tumor, caused in this case probably by the left lobe of the liver, was made. The patient was put upon an ample diet and received bromide of strontium. She was told to wear an abdominal bandage and to eat punctually, whether she had appetite or not, and without regard to pains. The patient recuperated quickly and began steadily to gain in weight. She has been well since.

Case IV.—September 14, 1900. Mrs. F——, fifty-two years old, complains since Christmas, 1899, of a feeling of distress in the stomach, occurring about one-half hour after meals and lasting just as long. Her appetite has always been good except during the last three to four weeks. She never vomited and never complained of eructations. The bowels were always more or less constipated. She says that some time ago she partly lost her sense of taste, so that she could not taste salt or vinegar. She also complains about a good deal of salivation, which troubles her very much. Since November, 1899, she has lost thirty pounds.

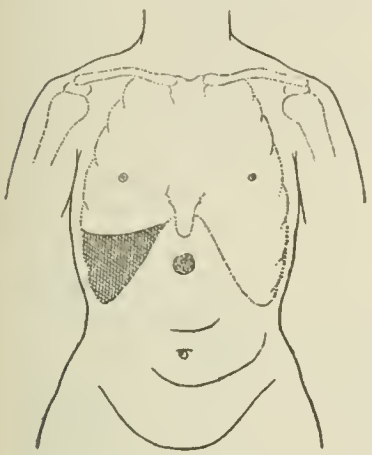

Fig. 1. Mrs. R. W——.

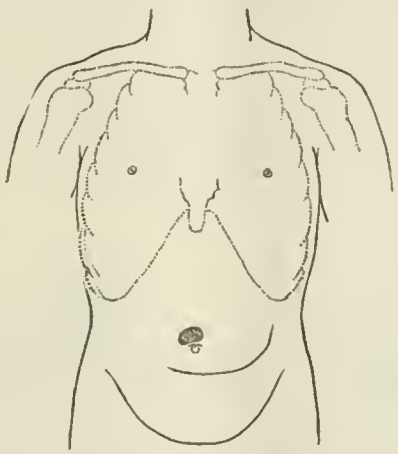

Fig. 2. Dr. F. D. A——.

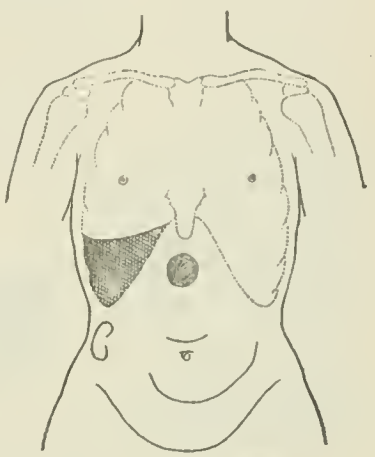

Fig. 3. Mrs. J. P. F——

The patient looks pale and anæmic. The skin of the arm can be lifted in large folds. The thoracic organs are intact. The tongue is only slightly coated. Palpation of the abdomen shows a resistance beginning about one finger to the left of the linea alba and extending three inches to the right, reaching from a little above the lower third between the processus ensiformis and navel to one finger below the umbilicus (Fig. 4). The stomach extends to more than a hand's width below the navel. The right kidney is movable in the third degree, the left in the second. The liver appears to be in a normal position. The glands are not swollen. The patellar reflexes are present. The urine contains neither albumin nor sugar.

Examination of the stomach one hour after Ewald's test breakfast shows the presence of HCl and the absence of lactic acid and of food particles from the previous day.

The high degree of enteroptosis and the fact that the resistance showed a smooth surface caused me to make a diagnosis of apparent tumor. The patient was told to take light food in sufficient quantity, and received condurango with cascara sagrada. About a week later she reported that she had followed the prescribed diet, that she had suffered less pain during this time, and that she had not lost in weight.

The time of observation is too short to exclude absolutely carcinoma, but it seems to me as if we had to deal only with an apparent tumor.

Case V.—September 8, 1900. Mrs. P——, about thirty-three years old, began to suffer from digestive disturbances about eight years ago, soon after marriage. She then lost her appetite, became pale, and

complained of pains in the stomach. She has suffered from constipation since childhood. About five years ago she was operated on for cysts of the ovaries, and both ovaries were removed. She now has a fair appetite, but complains of a good deal of gas and a heavy feeling after eating. Her bowels are slightly constipated. She sleeps fairly well, but has to urinate rather frequently.

Status præsens: The patient looks somewhat pale. The examination of the thoracic organs reveals nothing abnormal. On palpating the abdomen a resistance is felt beginning half-way between the ensiform process and the umbilicus and reaching down to two fingers above the navel (Fig. 5). It extends across the linea alba on both sides for a width of three and a half inches. The stomach extends to a hand's breadth below the umbilicus; the transverse colon can be palpated as a horizontal cord beneath the navel. The right kidney is movable in the fourth degree, the left in the third. The liver dulness does not reach beyond the right lower margin of the ribs. The patellar reflexes are present. The urine is free from albumin and sugar.

The examination of the stomach one hour after Ewald's test breakfast reveals the presence of HCl and a total acidity of 20. A diagnosis of enteroptosis and apparent tumor is made, and the patient is treated according to the usual methods for enteroptosis (bandage, ample food, iron).

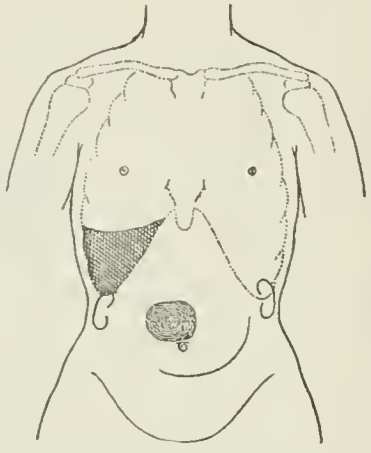

Fig. 4.—Mrs. A. F——.

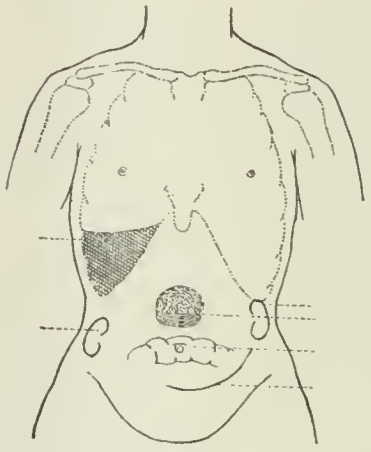

Fig. 5.—Mrs. P——.

Epicrisis. — In considering the cases described we see that in all there was apparently a tumor in the upper half of the abdomen, which could easily have been mistaken for a neoplasm. We now naturally ask ourselves how this apparent tumor is produced. The apparent tumor may be produced: (1) By a prolapse of the left lobe of the liver; (2) by exposure and thickening of the abdominal aorta; (3) by a hypertrophic condition of parts of the abdominal muscles; (4) by adhesions (?) around the small curvature of the stomach.

As I have not had occasion to make an autopsy in any of these cases (since as a rule most of them do well under rational treatment) it is natural that the points enumerated are of a purely theoretical nature, founded, however, upon the results of clinical examinations.

The left lobe of the liver may be the cause of the apparent tumor when it is situated in the median line directly under the ensiform process. Frequently we will get above the resistance, especially at the ensiform process, instead of liver dulness, a more tympanitic sound on percussion. The swelling in these cases is of considerable dimensions (size of a fist).

If the apparent tumor is caused by the aorta, it usually lies deep in the abdominal cavity, close to the spinal column, has an elongated shape, and pulsates strongly. The resistance is usually one to two thumbs in diameter and about two inches in length. Such a tumor is often mistaken for an aneurism.

The abdominal muscles are probably the cause of the tumor if it lies superficially and can be palpated to one side, either right or left, of the linea alba. The resistance usually runs horizontally and measures about one to one and a half inches in breadth by two to three inches in length; its surface is not globular like in tumors caused by the liver, but more flat, although it may be slightly rounded at the sides.

Adhesion of the stomach is hard to determine with certainty. The resistance felt is rather insignificant, small, lying generally in the smaller curvature of the stomach toward the pylorus, and does not show the characteristic distinctions of the three other groups. Whether the tumor belongs to one or other of the four groups is of less importance than the decision of the question, whether in a given case we have to deal with a real tumor (neoplasm) or only with an apparent tumor.

In apparent tumors the swelling presents a more or less smooth surface; at all events there are no distinct nodules. The tumor is not always felt with the same degree of distinctness and sometimes may escape palpation altogether. The tumor occupies the position described above, and a high degree of enteroptosis is usually associated with it. As further aids to diagnosis we have the course of the disease, which usually extends over years; the age (it may occur from the time of adolescence to old age), and the malnutrition, which generally is not of recent date but has lasted for a long time. If all these points are present together, the distinction from a real, malignant neoplasm is easy. Cases, however, occur in which the differential diagnosis is not so easy. In the first place, real neoplasms may at times present some of the characteristics of apparent tumors (*i.e.*, a smooth surface or an elongated shape, etc.); on the other hand, apparent tumors may simulate the characteristic appearance of carcinoma. Thus there may be a rapidly progressing emaciation as in the case of J. P. B—— and other facts pointing more to carcinoma may be present, and yet we have to deal with only an apparent tumor.

The cases detailed above are therefore of greater value because many of them have been observed for several years, and consequently the diagnosis of apparent tumor has been confirmed. If I be permitted to draw conclusions from my experience on this subject, I should say that in general the diagnosis of apparent tumor is easy, but that there are exceptional cases in which the decision, whether we have a real neoplasm before us or not, is exceedingly difficult. In these latter cases there is nothing left for us to do but to wait some time. Observation extending over a few weeks or months will then decide this question. In a neoplasm changes will occur (the swelling grows, the symptoms become worse), whereas an apparent tumor remains unchanged, or its symptoms rapidly diminish under suitable treatment.

Concerning the etiology of apparent tumors, it is evident from an examination of the above cases that they occur principally with pronounced enteroptosis. Great emaciation and the removal of certain abdominal organs (uterus, ovaries, etc.), which are of such great importance in the development and increase of enteroptosis, are also important factors in the development of the picture of apparent tumor.

As to treatment it is hardly necessary to remark that the apparent tumor itself does not need any curative measures. The original disease must be determined

and treated according to rational methods. Two points, however, are to be observed in the treatment of all these cases: First, the attention of the patient must be diverted from the existence of the tumor, or the patient's mind must be assured; secondly, sufficient nourishment must be prescribed and must be persisted in. In a great number of these patients sitophobia is present, and this must be overcome according to the

TABLE OF THE REST OF THE CASES OF APPARENT TUMOR, OBSERVED BY ME DURING 1897–1900.

No.	Name.	Age.	Disease.	Time of Observation.	Situation of tumor.	Remarks.
1.	Mrs. Rosa D.	40	Achylia gast., insuff. mitr., gastroptosis.	April 25, 1897.	Tumor lies 2 fingers below right margin of ribs, extends somewhat horizontally, and is of size of hen's egg.	
2.	Mr. F. W. A.	45	Hyperchlorhydria	June 26, 1897	Tumor lies horizontally in second third of line drawn from ensiform process to umbilicus, is size of small egg, and pulsates strongly.	
3.	Miss Mary S.	50	Gastroptosis.....	Oct. 22, 1897.	Tumor lies in middle between ensiform process and navel, extends horizontally, is about as large as a hen's egg.	Patient was operated on about one year before she saw me. A double nephrorrhaphy was done.
4.	Miss Anna H.	29	Enteroptosis, gastroptosis, ren mob. dext.	July 27, 1897.	Tumor lies under ensiform process, is of a smooth surface, and the size of a fist.	
5.	Mr. Otto S.	42	Gastroptosis, gastralgia.	Aug. 2, 1897.	Tumor lies 3 fingers below ensiform process, extends more to the right, and is about the size of a small apple.	Patient had lost considerably in weight, and I myself made a probable diagnosis of carcinoma of stomach. A year later I had the opportunity of seeing him again, and was astonished at his healthy appearance. Palpation of abdomen revealed at that time no tumor.
6.	Mrs. C. A.	60	Gastroptosis, hepatoptosis.	Aug. 26, 1897.	Tumor lies directly under ensiform process, has a smooth surface, and is of the size of a fist.	
7.	Mr. S. A. G.	48	Gastroptosis, hyperchlorhydria, neurasthenia.	Sept. 16, 1897.	Tumor lies somewhat to the right of the linea alba, 3 fingers under the right margin of ribs, is about the size of a hen's egg.	
8.	Miss Mary W.	23	Enteroptosis, ren mob. dext. (3d degree), gastralg. nervosa.	Nov. 3, 1897.	Tumor lies in median line, halfway between ensiform process and navel, is of elongated shape, pulsates strongly, and is of size of small egg.	
9	Mrs. H. F.	40	Gastroptosis, hepatoptosis, anæmia.	Jan. 15, 1898.	Tumor lies directly under the ensiform process, has a smooth surface, and is of the size of a fist.	
10.	Mrs. J. S. J.	32	Enteroptosis, achylia gastrica.	Feb. 17, 1898.	Tumor lies 3 fingers above umbilicus, runs horizontally, and is the size of a hen's egg.	
11.	Miss Lillie C.	25	Enteroptosis, hyperchlorhydria.	Nov. 22, 1898.	Tumor begins 2 fingers below ensiform process, lies in the median line, has a smooth surface, and is the size of a fist.	The patient was demonstrated in the winter of 1898, in one of the meetings of the Physicians of the German Hosp. and Disp. She had lost then over 30 lbs. She was suffering from vomiting and violent gastralgia. Patient was put on a nourishing diet and received alkalies and bromides. She rapidly gained over 30 lbs. in 3 to 4 months, and has remained free from distress ever since.
12.	Mr. W. J. W.	56	Enteroptosis, neurasthenia.	June 9, 1898.	Tumor lies in the middle between navel and symphysis, runs somewhat horizontally, and is of the size of a small egg.	
13.	Mrs. D. D.	57	Enteroptosis, hyperchlorhydria.	Aug. 9, 1898.	The tumor lies 2 fingers below ensiform process, has a smooth surface, and is of the size of a fist.	Patient had lost considerably in weight. Carcinoma of stomach had been diagnosed by several colleagues. One year later patient had gained 33 lbs. and felt well.
14.	Mrs. A. McG.	60	Dilatatio ventriculi.....	Dec. 3, 1898.	Tumor lies under ensiform process, has a smooth surface, and is of the size of a fist.	
15.	Mrs. Mary S.	43	Gastroptosis	Dec. 7, 1898.	Tumor lies more to the left of linea alba, somewhat above umbilicus, pulsates strongly, and is of the size of a hen's egg	
16	Mrs. W. E. M.	36	Enteroptosis, ren mob. dext.	Dec. 16, 1898.	Tumor begins about 1 to 2 fingers under the ensiform process, extends to just above the umbilicus, and has a smooth surface.	
17.	Mr. John G.	43	Atonia ventric., tuberc. pulm.	Dec. 19, 1898.	Tumor lies almost directly under ensiform process, has a smooth surface, and is about the size of a fist.	
18.	Mrs. McC	40	Enteroptosis, gastritis chron.	Dec. 20, 1898.	Tumor lies close under ensiform process, has a smooth round surface, and is the size of an apple	
19.	Rev. A. B.	57	Achylia gastrica.	Mar. 17, 1899.	Tumor lies under right margin of ribs, has a smooth surface, and is of the size of a small hen's egg.	
20.	Mrs. W. S. L.	56	Enteroptosis, anæmia.	April 25, 1899.	Tumor lies 3 fingers above the navel, extends more to the left, is somewhat elongated, of about the size of a goose egg, and pulsates strongly.	
21.	Mr. Marvin W.	27	Enteroptosis, ren mob. dext., hyperchlorhydria.	April 29, 1899.	Tumor lies to the right of the linea alba, under the margin of the ribs, is oval, and of the size of a hen's egg.	
22.	Miss L. P.	37	Enteroptosis, ren mob. dext., gastralgia.	May 8, 1899.	The tumor starts in the beginning of the second third of a line drawn from the ensiform process to the umbilicus, extends on both sides of linea alba, and is about the size of an apple.	
23.	Miss L....	33	Enteroptosis, ren mob. dext.	July 2, 1899	Tumor lies in left epigastrium close below margin of ribs, and is of the size of a goose egg.	
24.	Mrs. Gertrud S.	34	Ren mob. ut. (r. 3d, l. 2d degree).	Nov. 21, 1899.	Tumor lies beneath umbilicus in the region of the abdominal aorta, has an elongated shape, is of the size of a large hen's egg, and pulsates strongly.	
25.	Miss Ida U.	30	Enteroptosis, atonia ventr.	Nov. 27, 1899.	Tumor lies between ensiform process and navel, is of the size of an egg.	
26.	Mrs. J. R. B.	44	Enteroptosis, ren mob. ut. (r. 4th, l. 3d degree).	Nov. 29, 1899.	Tumor lies about in the middle between ensiform process and navel, and has the size of an egg.	
27.	Mrs. Josefine L.	29	Neurasthenia.....	Nov. 29, 1899.	Tumor lies 2 to 3 fingers above navel, extends more to the right of the linea alba, and is of the size of a large fist.	Double nephrorrhaphy, extirpation of uterus and both ovaries.
28.	Mrs. Lizzie H.	40	Enteroptosis, ren mob. dext.	Dec. 20, 1899.	Tumor extends to the right of the linea alba, lies 2 fingers above navel, and is nearly the size of a fist.	
29.	Mrs. Nora H.	30	Enteroptosis, ren mob. dext. (3d degree).	Mar. 21, 1900.	Tumor lies in the second third of a line drawn from the ensiform process to the navel, extends more to the left, and is about the size of an apple.	
30.	Miss Hattie C.	33	Enteroptosis, hepatoptosis, ren mob. dext. (4th degree).	April 1, 1900.	Tumor lies in median line, occupying second third of line drawn from ensiform process to navel, and is about the size of an apple.	
31.	Miss Alice M. B.	36	Enteroptosis.....	April 17, 1900.	Tumor lies somewhat to the right of the linea alba in the middle between ensiform process and navel, and is of the size of a large hen's egg.	
32.	Miss Olga L.	27	Enteroptosis, hepatoptosis (slight), ren mob. dext. (3d degree).	May 2, 1900.	Tumor lies 1 to 2 fingers above navel, extends more to the left than the right of the linea alba, and is of the size of a goose egg.	
33.	Mrs. E. W.	34	Enteroptosis, ren mob. ut. (r. 4th, l. 3d degree).	May 12, 1900.	The tumor lies 2 to 3 fingers below left margin of ribs, and is about the size of a goose egg.	
34.	Miss S....	24	Enteroptosis, hepatoptosis, ren mob. dext. (3d degree).	May 23, 1900.	Tumor lies to the left of linea alba in the middle between ensiform process and navel, and reaches to within 1 to 2 fingers above the latter.	
35.	Miss Mary G.	25	Enteroptosis, ren mob. ut. (r. 3d, l. 1st degree).	June 1, 1900.	The apparent tumor lies in the median line, 2 fingers above the navel, and is about the size of a goose egg.	
36.	Miss (Dr.) Florence W.	33	Enteroptosis, ren mob. dext. (2d degree).	Aug. 18, 1900.	Tumor lies on right side of linea alba, a little above umbilicus, and is about the size of a hen's egg.	
37.	Mrs. Rosie B.	40	Enteroptosis, ren mob. dext (4th degree), gastralgia	Sept 11, 1900.	Tumor lies in lower third, between ensiform process and navel, and extends to both sides of linea alba.	

principles laid down in my article on the diet of dyspeptics.

If both these indications are thoroughly met the main object has been accomplished, and a favorable result will soon follow.

MYASTHENIA GRAVIS WITH CLINICAL REPORT OF CASE.

BY SANGER BROWN, M.D.,

CHICAGO,

PROFESSOR OF NEUROLOGY, POST-GRADUATE MEDICAL SCHOOL; ASSOCIATE PROFESSOR, PRACTICE OF MEDICINE AND CLINICAL MEDICINE, MEDICAL DEPARTMENT, UNIVERSITY OF ILLINOIS; ATTENDING NEUROLOGIST TO ST. ELIZABETH'S HOSPITAL AND ST. LUKE'S HOSPITAL; CONSULTING NEUROLOGIST TO THE MARY THOMPSON HOSPITAL FOR WOMEN AND CHILDREN, AND TO THE HOME FOR DESTITUTE AND CRIPPLED CHILDREN.

CLINICAL Report of Case: The patient whose history follows came to me September 27th of this year through the courtesy of Dr. W. T. Montgomery, whom she had consulted for ocular disorder.

Miss A. B——, aged twenty-nine years, teacher, family history good, regular habits, happy in family and social relations, work congenial; always enjoyed good general health prior to present illness. She is of nervous temperament, but not an extreme example of that constitutional state, and has average endurance in both bodily and mental exercise. The skin is naturally clear, the body plump, and the tissues are firm.

About sixteen months ago, after having attended social functions rather freely during several months preceding, involving considerable loss of sleep, the patient was quite rapidly overtaken with a feeling of profound muscular exhaustion upon comparatively slight exertion; she could only with the greatest difficulty use her arms and legs, and could scarcely walk across the room or keep her arms raised in combing or doing up her hair. Diplopia and ptosis speedily became quite troublesome, the former being aggravated when the patient was in strong sunlight. Her voice soon became very distinctly nasal and her articulation thick and imperfect. She felt that the voice and speech changes resulted mainly from excessive weakness and fatigue in the tongue. When commencing to talk, if not tired, her voice and articulation would sound natural and no sense of exhaustion or effort would be felt; but soon the distressing symptoms would make their appearance and develop quite rapidly, till she could go on no longer. The muscles of mastication became so weak and tired while eating that she was often unable to finish a meal, though still quite hungry. There was occasional and not very severe palpitation, never globus or dyspnœa. There was sometimes slight humming in the ears. Occasionally there were slight frontal headache and pains shooting through the whole left side of the body; but all these latter symptoms were very infrequent and comparatively trivial. The mucous membranes of the mouth and nose became very uncomfortably dry at times. The hair and scalp have also been very dry and the hair has fallen out quite badly, but the skin generally has remained in good condition. Appetite, digestion, sleep, and menses are satisfactory. She suffers from habitual constipation, which is now somewhat aggravated.

There had been no mental depression further than what might naturally be expected as a result of discouragement incident to such an illness; no unnatural irritability, disturbance of the intellectual faculties or feelings at any time; no difficulty in holding the attention upon a given subject, nor amnesia, confusion of ideas, etc., as are so often seen in neurasthenics. The patient denied the possession of any irregular and unnatural appetites, propensities, or impulses.

Within a week or two after the symptoms appeared she became unable longer to continue her work, and then spent several months resting, much of the time in the open air and surrounded by favorable hygienic influences. A marked improvement took place, so that after a rest of four months she resumed her school work; but in a few weeks her former symptoms returned and have persisted with some variations, or perhaps more properly, partial remissions, down to the present time. She has not been able to do her hair for six months and usually after a short walk has not strength enough to cross her legs when sitting. The symptoms referable to the tongue and muscles of mastication—the difficulty of speech, nasal voice, and indistinct utterance—remain as above described; and so, indeed, do all of the other symptoms, except the diplopia and ptosis, which are less frequently observed and less severe than at first. She has lost about fifteen pounds in weight since her illness began.

Examination: The patient is highly intelligent, cheerful, well developed, well formed, well nourished, and of medium size; the skin is soft, elastic, and of good color; the hair is rather thin and dry, but I could discover no obvious defect in the condition of the scalp; the reflexes are all normal but lively; voluntary motion is possible in every direction and there is no inco-ordination; the strength is greatly reduced, the patient scarcely being able to raise the indicator of a dynamometer to 5°, when 50 to 60° would be about the average for a healthy woman of her age and development. I did not make an electric test nor did I try to exhaust the knee jerks by repetition, for reasons personal to the patient. There was no suspicion of muscular atrophy or deformity anywhere; neither was there any disorder of sensation of any kind; no pain or tenderness upon pressure was discoverable, and indeed I sought in vain for any evidences of hysteria.

The eyes were tested by Dr. W. T. Montgomery, of this city, the same day that I made my examination, and according to his notes which he kindly gave me, after some slight astigmatism was corrected vision was normal. The pupils, which were quite large, reacted well to both light and accommodation, though rather slowly. The fundus was normal. There was diplopia when the eyes were strongly turned either to the right or to the left, due evidently to weakness of the abducens. There was slight but distinct ptosis, equal on both sides, and the movements of the lids were notably slow. The visual fields were not tested. I regret that this was not done and also that an attempt was not made to exhaust the faradic excitability of the muscles. To my mind, however, the diagnosis is entirely clear in the absence of these tests.

Historically I will only say that the names of Wilks and Erb are connected with the earliest reported cases of this disease, which were recorded in the late seventies. Since then the subject has attracted considerable attention on the part of European neurologists; at least I judge so from the numerous references to it in the "German Year-Book of Nervous Diseases."

In this country, Dr. Archibald Church has for several years past given abstracts of cases in the "American Year-Book." He has also given a concise description of the disease in his text-book. Dana likewise describes it in his work, as also does Joseph Collins

quite elaborately in the "Twentieth Century Practice." These authors, in common with many others, designate it by the term "asthenic bulbar paralysis." Cases have likewise been reported as "bulbar paralysis without any discoverable anatomical change." In the light of extended experience and observation these names appear misleading and possibly they have not yet taken so firm a position in literature that they may not be replaced. So far no anatomical changes have been discovered; hence the propriety of adopting a name which shall embrace the most salient clinical features, while it does not convey any unwarranted intimations as to the seat of the disease and its pathology. For these reasons I prefer the term I have used.

The name myasthenia gravis has been employed by Campbell and Bramwell in a recent article in *Brain* (summer number, 1900), in which they present a critical digest of the disorder, with an appendix containing notes of sixty cases, many completed by autopsy. I have drawn freely upon their article in the preparation of this paper. So far as I am aware, it is the most complete presentation of the subject at present available. They say that hitherto only four cases have been published in America; so that either the disease must be comparatively rare or its salient features have not been widely and clearly understood.

Etiology: Thirty-five and twenty-four are the customary ages for men and women respectively, while their liability is about equal. Some prostrating disease, as influenza, typhoid fever, etc., quite frequently precedes the affection, and anæmia is often met with in women. Alcohol and syphilis are not of especial significance; neither are hereditary influences.

Onset: This is usually gradual, but occasionally the disease develops very rapidly, almost suddenly. Most frequently the first symptom is the characteristic weakness of some of the muscles supplied by the cranial nerves, the external ocular muscles, the muscles of mastication and the tongue; but it may begin in the extremities, the muscles that support the head, or, indeed, any of the functionally grouped voluntary muscles.

Symptoms: One of the most prominent characteristics of the disease is the profound exhaustion, amounting in many cases to temporary but almost complete paralysis of the functionally grouped voluntary muscles upon comparatively slight exercise. The muscular symptoms are essentially bilateral, though there may be considerable variation between the two sides. Ptosis and diplopia are very common in the earlier stages. Irregular nystagmoid movements may be induced by lateral conjugate deviation of the eyes, and as might be expected, the eyes tire easily. The pupils are usually unaffected. The muscles of mastication are very constantly implicated and often among the first to be complained of. The patient often fails to finish his meal, especially the evening meal, on account of fatigue in these muscles, and the jaw is not infrequently supported by the hand during mastication and while the patient is at rest. The muscles of the upper face are likely to be as much affected as those of the lower, while these latter suffer much less than in developed cases of true bulbar paralysis, so that the facial expression differs very much from that observed in the latter disease. The muscles of deglutition are often weak, and liquids regurgitate through the nose on account of weakness of the palate. The pharyngeal reflex is often diminished or absent, hence the liability to choke while eating. I did not examine the larynx nor the pharynx in the case above reported, but the patient did not complain of choking or difficulty in swallowing. Paralysis of the laryngeal muscles is rare, but a feeling of aching and stiffness in the tongue, especially after eating and speaking, is common. Characteristic alterations in speech are almost invariable. It becomes nasal shortly after the patient begins to speak, and the words grow more and more indistinct until he is finally forced to desist from sheer exhaustion. Inability to support the head is common, because the muscles concerned are in constant action when the patient assumes an erect posture, and are therefore constantly the seat of the peculiar exhaustion. When the respiratory muscles become involved, they cannot recuperate by rest, and thus a fatal result may ensue. In like manner any of the voluntary muscles may suffer, giving rise to symptoms as various as their normal functions. The symptoms may almost wholly and unexpectedly remit for several days together.

Emotional excitement, cold weather, and menstruation have each been known to aggravate the complaint.

The muscles react normally to electricity, but are speedily exhausted by the faradic current in many cases. After rest they respond again. This is known as the myasthenic reaction. Atrophy is never present in pure cases and the various skin reflexes and muscle jerks are not materially disordered. The sphincters are never disturbed and there are no trophic or sensory changes. Muscular inco-ordination has never been observed.

Morbid Anatomy and Pathology: Though in the sixty cases above referred to seventeen came to autopsy, some of which were examined by highly skilled investigators, who employed the most modern microscopical technique, in only six cases was anything found which could possibly account for the symptoms.

Many plausible and ingenious hypotheses have been advanced in explanation of the symptoms, but they cannot profitably be discussed within the limits of this paper. I will say in this place only that the fact that in severe cases the symptoms sometimes vanish quite rapidly and for an indefinite period, and that even in fatal cases no anatomical lesion can be demonstrated, suggests a toxic influence powerful enough to inhibit function, but of such a nature as to produce no demonstrable changes in the organic elements concerned. Also the nature and distribution of the symptoms point to the bodies of the peripheral motor neurons as the main seat of the attack of this toxin. The test recently made by Dr. Farquhar Buzzard,[1] of London, upon a typical case appears to demonstrate conclusively that the paralysis is wholly due to a failure of nervous energy. In this test he simply exhausted the muscles to faradism and found that they still reacted perfectly well to galvanism; that is to say, temporary degeneration reaction was present, which of course always implies functional integrity of the muscles and at the same time suspension of the functional activity of their peripheral motor neurons.

Diagnosis: This is very important, because, unless the physician happen to have the salient features of the disease in mind, the frequently satisfactory condition of the general health of the patient, together with the nature of the symptoms, is not likely to suggest any immediate or even remote danger to life.

The diagnosis is easy when the peculiar exhaustion appears in the external ocular muscles, the tongue, and the muscles of mastication, and when the peculiarities in speech are manifest.

But, especially in the early stages of slowly developing cases of myasthenia gravis, the frequent and almost infinite variety of combinations between general neurasthenia and hysteria have to be reckoned with, because in some of these affiliations profound muscular exhaustion after comparatively slight exercise is not uncommon. Neither is a peculiar loss of power (stiffness) in the tongue and even other muscles supplied by the cranial nerves uncommon, while ptosis

[1] Foot note in Campbell and Bramwell's article previously referred to.

and diplopia are frequently met with. In these conditions, however, the underlying state is usually apparent, and besides, while there is some slight similarity in the symptoms themselves, the differences are quite conspicuous. There is more of a general and lasting prostration and less of a temporary paralysis. The ptosis, diplopia, and stiffness of the tongue and indeed of various other muscles supplied by the cranial nerves are, for the most part, independent of exercise.

An association between myasthenia gravis and hysteria may present very great difficulties of diagnosis in which, if the former disease were not detected, an apparent simple hysteria might prove fatal.

When the disease is far enough advanced to suggest bulbar palsy or polioencephalitis, the course, the distribution of the weakness, and the presence of muscular atrophy in these latter instances are significant.

Prognosis: Of the sixty cases above referred to, twenty-three ended fatally, the average duration of the disease being one and a half years. Paralysis of the respiratory muscles resulting in asphyxia is usually the essential cause of death—a fact which greatly increases the gravity of any sort of pulmonary disorder in these patients. Some patients improve and all symptoms disappear for months or even years, while others recover permanently. The proportion of these latter will, I believe, be much increased when the disease comes to receive general recognition.

Dr. Hall reports a typical case in *Brain* (summer number, 1900) in which a woman of forty-four died quite suddenly of this disease from failure of the respiratory muscles four months from the rather rapid onset. The post-mortem findings were negative, though a thorough microscopical examination was made. This case improved very much for a few weeks, after the disease had lasted two months, under isolation, overfeeding, electricity, and massage, but grew worse again while these measures were still being employed.

Treatment: I cannot speak of the treatment from personal experience. Many drugs have been tried, but so far none has been found with any specific influence over the disease. Buzzard tried in two cases strychnine hypodermically in gr. $\frac{1}{6}$ doses daily without benefit; but I should like to see nitrate of strychnine tried hypodermically in gr. $\frac{1}{15}$ doses daily, as has been done with considerable success in certain cases of progressive degeneration of the peripheral neurons (progressive muscular atrophy of the spinal form). Of course all general measures calculated to maintain a high standard of the general health, consistent with the symptoms, should be employed. If, finally, the stomach tube has to be used, the paralysis of the muscles used in swallowing demands the exercise of special caution.

105 State Street.

The Relationship between Cancer and Tuberculosis.—I. D. Nagle gives a list of investigators who have studied the relationship of these two diseases. Burdel declares that the appearance of cancer and tuberculosis in the same family cannot be due solely to accident, but must be the result of an intimate relation between the two diseases. Croizet reports twenty-four cases and A. Gouin forty-two cases of coincidence of cancer and tuberculosis. The author has in the past ten years studied the family history of more than seven hundred tuberculous patients, and found that in eighty cases the pre-existence of cancer in one or more parents was discovered. He firmly adheres to the belief expressed by Carmichael in 1809, that "carcinoma and tuberculosis belong to the same family of diseases."—*The Medical Examiner and Practitioner*, October, 1900.

NOTES ON TYPHOID FEVER, WITH A REPORT OF FIFTEEN CASES.

By D. E. KEEFE, M.D.,

SPRINGFIELD, MASS.,

VISITING PHYSICIAN TO THE MERCY HOSPITAL.

The necessary limitations of a paper for the Medical Record, as well as the great extent and interest of the subject, to say nothing of its familiarity, preclude my attempting an exhaustive discussion of typhoid fever or of giving a complete résumé of its literature. I shall content myself, therefore, with a very cursory report of fifteen cases that came under my care during my present term of service at the Mercy Hospital, making observations upon them and upon the subject in general.

Etiology.—The causative factors in this fever are undoubtedly the Eberth bacillus, a susceptibility or predisposition, or a want of resistance on the part of the patient, or a combination of all these circumstances. True, this bacillus conforms to but two of the three conditions laid down in Koch's law, namely, it is always present in the disease, it grows outside of the body, but inoculations of its cultures have, so far, failed to produce the disease. Nevertheless, the experiments of Dr. L. Remey seem to have disposed of the claims of the colon bacillus as a causative factor and established Eberth's as the only true cause.

Incubation.—Until very recently the incubation period of typhoid fever was not definitely known, but the experiments of Vaughn and others have established it as from two to eight days, and the infection may be carried on the person or clothing for eight weeks.

Diagnosis.—The prime difficulties in the prompt diagnosis of typhoid fever in private practice are its insidious onset, and the time permitted to elapse before a physician is summoned. We thus lose the great advantage of observing the typical range of temperature in its development. These circumstances are aggravated by the atypical form and the remittent character in which it sometimes presents itself. This atypical form is due either to a difference in the dosage of the infecting germs, to mixed infection, a difference in the resisting-power of the patient, or to all these combined. Finally, the extent of the bronchitis or other initial complication may be a factor in its causation. Be this as it may, in hospital practice we are nearly always deprived of the benefit of the observation of its early symptoms, and frequently have but a very incomplete history, and that often entirely untrustworthy. There is scarcely one of the acute infectious diseases so protean in form or so difficult of diagnosis in the early stage as typhoid fever. If it is distinguished for one thing more than another, it is for its atypical rather than regular classical form. In the words of a great author, "Clinically the disease is marked by fever, a rose-colored eruption, diarrhœa, abdominal tenderness, tympanites, and enlargement of the spleen; but these are extremely inconstant, and even the fever varies in its character." In pneumonia we have always the dulness on percussion, and the increased fremitus; in scarlet fever, the angina, rash, and fever. But in typhoid fever there is not a single symptom invariably present, not one of the classical or pathognomonic symptoms but may be absent in a given case, even the fever itself, and we may have an afebrile typhoid. In addition to the symptoms before referred to, we have those of lesser importance, as epistaxis, cephalalgia, prominent and sensitive abdomen, typhoid tongue, gurgling, and others that will readily occur to the reader. Since I refer to most of them in another place, I need not waste space here with their further enumeration.

Widal Reaction.—Thanks to the labors of Pfeiffer,

Elsner, Widal, and their co-workers, the last few years have witnessed a great advance in our ability to diagnose typhoid fever. This is due to what is known as Widal's test, or reaction, and depends upon the known behavior of the Eberth bacilli in the presence of an immunized or specific blood or blood serum; namely, they lose their motility, clump together, and sink to the bottom of the liquid, the supernatant fluid becoming comparatively clear. Pfeiffer was the first to notice these phenomena taking place in the human body. It remained for Widal to apply it to typhoid fever outside of the body, to simplify it and make its application practicable. I am aware that there are those who question both the utility and the constancy of this reaction, who assert that it is neither confined to typhoid fever, nor conclusive of it, nor is it invariably present; and finally, that it is present in many other diseased conditions. It is true that many circumstances may exist in an organism affected with typhoid, such as mixed infection and other conditions not yet well understood. These conditions may affect the reaction two or three times in a hundred, but, making all due allowance for such cases, its importance cannot be overestimated. The fact that Widal, by its use alone, diagnosed five hundred cases without an error, should be a sufficient answer to such objections. Let me here quote the words of Widal in his last paper on this subject: "A positive reaction should be considered a sign of certitude of typhoid fever. A negative one furnishes a probability against it, but only a probability." Furthermore, Pick found the reaction only in typhoid fever. In the "American Year Book for 1898," pages 31 and 32, is presented one table of 174 cases of typhoid fever with all positive, and 164 cases of non-typhoid with 151 negative, reactions; another table contains 2,283 cases of typhoid with ninety-five per cent. of positive, and 1,350 non-typhoid with 98.4 per cent. of negative, reactions. Such statistics, supplemented as they are by the firm support of Fränkel, W. H. Welch, Stewart, Wilson, Liebermeister, Pfuhl, and Johnson and McTaggart, should be enough to establish the Widal test as the great, I might say the almost certain, test for typhoid infection. This list could be multiplied indefinitely with names of the most eminent men in the medical profession, especially in the department of bacteriology.

Let me now advert briefly to another tes that has been used somewhat at the Mercy Hospital. I refer to Ehrlich's diazo reaction. This is a urinary test, and consists in a reaction taking place between a solution of fifty parts sulphanilic acid and one thousand parts hydrochloric on the one hand, and a two-per-cent. solution of sodium nitrate and ammonia, with which the suspected urine is allowed to come slowly in contact in a test tube, just as it is in the nitric-acid test for albumin. (A deep brownish-red ring is a proof of infection.) This reaction may be present before the appearance of the rash and persist until the twenty-second day. Its value is lessened, however, by its occurrence in miliary tuberculosis, and occasionally in cases associated with high fever. Osler found it in twenty-two out of twenty-six cases of typhoid fever.

Mixed Infection. There are still those who question the coexistence of the typhoid bacillus and the plasmodium of malaria. They insist that typho-malarial fever is nothing more nor less than a remittent or continued malarial fever with typhoidal symptoms. True, the blood of our typhoid cases at the hospital was frequently tested for plasmodia with negative results in all but one case, and this was undoubtedly one of mixed infection; still there are symptoms in many cases of typhoid fever that cannot be accounted for on any other hypothesis than that of mixed infection. There are the recurring chills, the atypical form, and the remittent character, to say nothing of the double quotidian curve. There is also the great swing of the fever wave, its height and depth. As bacteriology increases both in the number and enthusiasm of its workers, I firmly believe that mixed infection will, in the near future, be established as a certainty. Indeed, we may say the light is already beginning to shine, when a man of such attainments as V. C. Vaughn declares in its favor and furnishes proof of its existence. A. J. Lartigau reports the diplococcus lanceolatus and the streptococcus pyogenes present in company with the bacillus typhosus. Osler acknowledges a qualified belief in the idea of mixed infection, and cases are reported by J. M. DaCosta, C. F. Craig, A. Stengal, M. Goltman, and T. F. Raven; while Dr. Woodard is a most ardent advocate of the doctrine.

Prognosis.—The heart in typhoid is normally relatively slow, not maintaining its relation with the fever. So a weak heart, inaudible first sound, a change in the heart's rhythm are most unfavorable, as are obesity, alcoholism, profuse hemorrhage, nervous tremors, and serious involvement of the nervous system, active delirium, too profuse diarrhœa.

Mortality Rate.—The mortality rate varies with different epidemics, and with the different treatments. Osler gives it as ten to thirty per cent.; J. C. Wilson reports one series of selected cases at the German Hospital with 3.4 per cent., and another series of two hundred and seventeen cases with 7.8 per cent.; A. V. Meigs reports two hundred and fourteen cases in the Pennsylvania Hospital with a mortality rate of 8.88 per cent.; three hundred and eighty-nine cases were treated at the Johns Hopkins Hospital in six years, with a rate of twenty-four per cent. The mortality rate at the Montreal General Hospital for twenty years was 11.2 per cent.; and Murchison, in summing up an immense number of cases, made the death rate nineteen per cent. There were one hundred and twenty-six cases treated at the Mercy Hospital with twelve deaths, making a rate of 9.08 per cent. The fifteen cases here reported all resulted in recovery. There can be no question that the Brand treatment has reduced the mortality rate to between four and seven per cent. Although the mortality of children is generally thought to be small in typhoid fever, Dr. Abraham Jacobi reports a series of cases in the children's pavilion of Bellevue Hospital, having a death rate of twenty per cent., and he refers to the series of Oesterlin with twenty-two per cent. and Friederich with twenty-three per cent.

Symptoms and Treatment.—Of my cases the ages ranged from seven to forty-five years. The attacks were quite severe in one-third, the remaining two-thirds being mild. Two of the mild ones proved abortive. Widal's test gave a positive reaction in all but one, and in this one the plasmodium of malaria was found. The disease, however, failed to respond to cinchonization and continued on its course, and a long course it proved. This was apparently a case of mixed infection. The diazo reaction was used in one-third of the cases, with all positive reactions. Many were tested for the presence of plasmodium, especially when any deviation from the normal was observed. Limited though this number of cases is, it embraced some without diarrhœa, some without rose spots, and as for the typical range of temperature, that was more noticed in the breach than in the observance. Epistaxis was present in but one case, and as to the prominent sensitive abdomen, it was no more in evidence than the scaphoid or boat-shaped one. Tympanites was frequently present, but not invariably. The pale olive, leaden look was no more constant than the suffused, flushed countenance, especially until the latter part of a long run of the fever. The enlargement of the spleen was not

a very constant symptom. I may say parenthetically that making out the spleen, especially in the presence of a tympanitic abdomen, and unless the enlargement is very considerable, is a task not always satisfactorily accomplished. Nervous symptoms, as delirium, carphology, and subsultus tendinum, were not present to any unpleasant degree except in one case; constipation was present more frequently than diarrhœa; indeed, the latter was not prevalent to any such extent as to call for interference except in one case. Abdominal pain was never a subject of complaint. The tongue generally conformed to what one would expect a well-developed typhoid tongue to do, namely, to be first covered with a white coat, which gradually cleaned from the edges toward the centre; to be replaced by a brown coat, or to remain clean, red, beefy, and become fissured. There were, however, many cases in which the tongue retained its first white coat throughout the disease. True, the coat grew a little yellow with time, but was not exfoliated and remained moist. After all, the cephalalgia was the most constant symptom, though the pain was not of an excruciating character. Bronchitis was an almost universally present initial symptom. Albuminuria was present in a majority of the cases, as were hyaline and frequently fine granular casts, and they persisted in some of the cases long after defervescence. One of the cases was complicated by true nephritis with three to six per cent. of albumin and fine and coarse granular, epithelial, and hyaline casts, notwithstanding which the patient is convalescing. I may add that this patient had repeated hemorrhages. An interesting complication was a suppurative appendicitis, and an appendectomy was done by Dr. Weiser; the patient made a good recovery, except that he had an unusually long run of the fever. I have seen two such cases elsewhere reported. One little girl was sent in for operation for a supposed appendicitis; she had the most sensitive abdomen of the series, but made a good recovery without operation.

The treatment that in my judgment offers the greatest promise, both as prophylactic and curative, is orrhotherapy. I could report many favorable cases treated in this manner, but shall content myself with reporting one instance of its use for prophylaxis or immunization. Professor Wright, of Netley, inoculated about three thousand soldiers for service in India, where typhoid is very prevalent. He subsequently observed the disease rate and the death rate in the inoculated as compared with those not inoculated. The result was that the disease rate in the uninoculated was treble and the death rate nearly double that of the inoculated.

There have been many kinds of treatment proposed, as the abortive, the antiseptic, the normal salt, and the cathartic. A careful study of the literature convinces me that, with our present knowledge, we have no medicinal agents able to abort or cure typhoid fever, or, indeed, any of the acute infectious diseases. I do not say that there may never be a combination of circumstances when the proper dose given at just the proper moment would not exert an influence for good, and perchance prove curative. Still, I believe this is an exceptional combination. Such treatment may, however, promote the comfort of the patient and so enable him more easily and successfully to bear the burden of his sickness. In consequence of this belief it will be readily appreciated that my treatment was substantially *nil*, and so indeed it was. Some medicines were employed, but only tentatively, one medicine in this case and another in that, because each bore some relation to the prevailing symptom, but principally as placebos. The medicines employed consisted of gr. v. salol in one, and the same with gr. xv. subnitrate of bismuth in another; gtt. x. tincture of nux vomica, or gr. $\frac{1}{30}$ strychnine in another; gtt. vi. dilute hydrochloric acid, or a teaspoonful of compound tincture of cinchona, in the next—all given usually three times daily. For the intestinal hemorrhages, lead and opium pills, one every four hours, and a mixture containing to each dose gtt. xv. fluid extract of ergot and gtt. x. each of tincture digitalis and colorless fluid extract hydrastis canadensis. For my severest cases I gave a few doses of gr. x. phenacetin in the afternoon, accompanied by gtt. xx. tincture of digitalis, and on one occasion gr. xxx. of quinine, cautioning the nurse to administer whiskey and digitalis should too much depression follow. The constipation was controlled by calomel, citrate of magnesia, cascara, or salts, the latter generally having the preference. On one or two occasions an hypnotic was required, when gr. xv. of trional was given. As before stated, I consider the medicinal treatment of secondary importance. That of paramount importance is the non-medicinal. The treatment by cold was first proposed by Currie, of Liverpool, at the end of the last century, but there being at that time no clinical thermometers to measure either its immediate or ultimate effects, it became neglected and finally disused. It remained for Brand, of Stettin, to bring it again to the notice of the profession and to formulate rules for its employment. Although it was condemned by so close an observer as the late Prof. Alfred Loomis, and adopted only in a modified manner by Professor Osler, I consider it rational, safe, and the most effective treatment for hyperpyrexia.

I did not attempt to carry out the Brand treatment in my cases by reason of lack of facilities on the one hand, and on the other of an indisposition to resort to such radical treatment, especially since my cases, with one exception, were not sufficiently grave. Moreover, the measures resorted to seemed to accomplish all that was desired. The application of cold was effected by ice in rubber bags, applied around the head and on the abdomen. These bags were wrapped in towels to prevent wetting the patient and bedding by precipitation of watery vapor from the atmosphere, caused by its contact with the cold rubber. In addition to this in my most severe case a cold coil was constantly applied to the abdomen, sponging was done every two hours, and late in the afternoon a sheet wet in cold water was wrapped round the patient. This, and a little attention to the mouth and the changing of bed and body linen, composed the most important part of the treatment. It goes without saying that the linen was removed and disinfected as often as soiled, that the excrements were received into a 1:20 carbolic-acid solution, covered with a like solution stirred up to mix thoroughly, and immediately disposed of. The only tangible effect of the digitalis was to produce a great increase in the excretion of urine, and of strychnine that it accentuated the effect of the digitalis. I was not able to realize any useful effect from whiskey, a few one-ounce doses of which were given experimentally.

Diet.—The diet consisted for the most part of milk, a glass of which was usually given every two hours. This was varied or supplemented by beef tea, thin broths, thin gruels, and egg-water, as demanded by different indications.

The Diet in the Acute Stage of Pneumonia.—Andrew H. Smith prefers egg-water and peptonized milk. The former is prepared by squeezing the albumen of one or two eggs through a cloth and adding half a pint of water and a pinch of salt. This, or beef tea, may be given alternately with milk at the rate of three ounces of either every three hours. If flatulency occurs koumyss or matzoon may be substituted for the milk.—*International Medical Magazine*, October, 1900.

THE VALUE OF THERMAL CARBONATED SALINE BATHS IN GYNÆCOLOGY.

By S. W. BANDLER, M.D.,

NEW YORK.

We find in gynæcological practice a very large number of cases which, though the symptoms may be severe, deserve conservative treatment for the following reasons: (1) Because after a long treatment they may be considerably improved; (2) because their symptoms, as local affections, do not justify the risk of operative interference; (3) because the desire for future pregnancy is a justification for conservatism; (4) because the cases after acute inflammations are suited to conservative methods only; (5) because such methods are a valuable preliminary to subsequent operation; and finally (6), because the local affection is only a part of a generally weakened physical state.

Among these conditions are included certain forms of metritis, parametritis, pelveo-peritonitis, salpingitis, hydrosalpinx, pyosalpinx, etc. A large proportion of cases have these affections to a slight degree, but combined with them are displacements of the uterus and adnexa with chronic congestion or venous stasis in the pelvis, with reflex and constitutional symptoms. Not infrequently ren mobilis, gastroptosis, and enteroptosis are found coexisting. These patients often possess a flabbiness and lack of elasticity, which is by no means the result of the gynæcological condition, so that we are compelled to consider the latter as part of a general state.

From the gynæcological standpoint we name this condition hysteroptosis. These various conditions are through local treatment, and especially through rest, open to improvement. Especially is rest an important and often astonishingly valuable means in aiding resorption and relieving congestion. If, combined with local treatment, attention is given to existing weakness, anæmia, and circulatory disturbances, then we obtain decidedly better results. Conditions such as rheumatism, gout, and auto-intoxication must be taken into consideration. The important element in the treatment of exudates and congestions consists in restoring a normal pelvic and general circulation, and in toning up the muscular structures of the pelvis and the body generally.

It was the frequency with which the cases of hysteroptosis came under my observation that influenced me to look to constitutional treatment for their relief in place of continued local applications for these symptoms, among which leucorrhœa, pelvic looseness, and especially backache may be mentioned. The method which has the greatest and most rapid effect, and which in certain cases seems almost specific, is hydrotherapy, under which we understand both thermal and chemical stimuli. A study of the general action of thermal carbonated saline baths confirms me in the belief that we have in them an excellent method of treatment for such cases, especially to promote the resorption of exudates and inflammations, and for the relief of congestions. The results obtained in the treatment under my own direction in the clinic Abel, Berlin, of twenty-one selected cases with various gynæcological ailments amply justify the acceptance of this method, and future experience will suffice to fix the limitations and indications. Among the most gratifying results were those obtained in the treatment of pyosalpinx. This paper deals, therefore, with the treatment of (1) exudates, infiltrates, and inflammations; (2) pelvic congestions; (3) hysteroptoses.

Winternitz and his school have taught us the effect of baths of different temperatures, and we have in hydrotherapy a powerful oxidation therapy, whereby through thermal and mechanical influences, activity and function, hunger and revulsion can be produced in the cell. Hydrotherapy is a powerful curative method, since thermal and mechanical processes are the normal stimuli which arouse, strengthen, and regulate our organic functions in a physiological way. An important effect of hydrotherapy results through its influence in changing and altering the blood distribution through the withdrawal of blood from congested and overloaded organs, whereby circulatory disturbances may be corrected. The value of such a change, and its influence upon congestions in the pelvis, may be recognized when we consider that, next to the peripheral, the region of the pelvic vessels with their large venous plexuses is one of the most important elements in regulating blood division and blood pressure. Since the blood and lymph channels furnish the material for the organic functions and for the nutrition of the organs, the circulation of any part is one of the most important factors in preserving its tone.

The use of cold water influences also a change in the morphological character of the blood. It causes not alone an increase in the number of leucocytes, but likewise a decided increase in the number of red blood corpuscles. A necessary factor in obtaining this result is the production of a decided hyperæmia of the skin. If the skin remains cool for a considerable time, and if a complete reaction is not excited, this change does not result; for then these cells, probably preformed blood cells, do not enter the general circulation. Since after warm baths the increase in the number of erythrocytes is much less, this increase rests clearly upon changes in the circulation, in the heart's action, and in vessel tonus and tissue tonus. The blood richer in cells, richer in oxygen, makes the entire tissue change more complete, and causes an increased consumption of oxygen, and an increased giving off of CO_2. The resulting increased production of heat is reflexly regulated, and not by the degree or amount of heat withdrawn, but by the degree of the thermal nerve stimulus. The increased tissue metamorphosis brought about reflexly through the influence of cold causes no increased consumption of albumin, but concerns chiefly the elements.

The combination of cold with a mechanical stimulus increases the reaction. Cold baths cause a contraction of the peripheral vessels and bring about, through thermal stimulation of the vagus, a slowing of the pulse, increase the oxidation processes in the body, and exert a stimulating effect on the central nervous system. An important result of the contracting influence of cold is the increase in the venous tonus. Since cold temperatures oppose the dilatation of the peripheral vessels, mechanical stimuli are necessary to bring about a dilatation, so that in hydrotherapy the mechanical stimulation, frottement, must be combined with a thermal procedure to bring about peripheral relaxation; for only with the resulting sinking of the tension and of the blood pressure (reaction) comes a feeling of well-being, and only those thermal processes which influence the heat balance of the body can be considered trophic, and only those which lead to reaction tonic.

A warm full bath causes an increase in the rapidity of the pulse, which persists after the bath. This occurs through its influence on the peripheral nerve supply, which reflexly acts upon the vagus centre, and which stimulates the accelerantes of the vagus. Such a bath can through weakening of the venous tonus cause an increased resistance in the minor circulation, whereby, in spite of increased work on the part of the heart, no bettering of the circulation results. This is a weakening influence, since the heart is sufficient only when it is able to force the blood to the most distant organs, in whose capillaries alone tissue metabolism takes place. A warm full bath causes usually no increased

demand for nutrition and exerts no stimulating effect on the central nervous system. The following objections may be raised also against cold fresh-water baths:

1. A mechanical frottement of the skin during and after the bath is necessary to bring about a complete reaction.

2. Many patients cannot stand the first shock of the cold water.

3. The effect of the bath lasts but a short time.

4. The increased tissue metabolism is not so great as in other baths.

We can substitute for the thermal and mechanical stimuli chemical stimuli, and can likewise overcome the shock of the cold water, if the bath contain chemical ingredients which exert a frottement of the entire periphery. Through varying proportions of the chemical ingredients we can regulate the strength of the stimulus. We can in a bath of indifferent temperature without shock in this way obtain the same and more lasting stimuli than by thermal means, and can cause by chemical combinations a more decided increase in the processes of oxidation. We are able by such baths to bring about a lasting protection and rest to the heart, and an improved state of the circulation. An important element is the ability to bring about a decided and increased resorption of broken-down tissue products.
